### ILLINOIS BIOLOGICAL MONOGRAPHS

THE ILLINOIS BIOLOGICAL MONOGRAPHS is a serial published quarterly by the University of Illinois. It is the purpose of the publication to present in monographic form research contributions of especial merit and of somewhat extended character. Each volume will include about 500 pages and 20 or more full page plates. The series may be obtained at a subscription price of three dollars yearly. Individual numbers will be sold separately at prices determined by the size and amount of illustration contained in the particular number.

#### Vol. I

- Nos. 1 and 2. A Revision of the Cestode family Proteocephalidae. With 16 plates. By G. R. La Rue. \$2.00.  
 No. 3. Studies on the Cestode family Anoplocephalidae. With 6 plates. By H. Douthitt. 80 cts.  
 No. 4. Some North American Larval Trematodes. With 8 plates. By W. W. Cort. \$1.20.

#### Vol. II

- No. 1. Classification of Lepidopterous larvae. With 10 plates. By S. B. Fracker. \$1.50.  
 No. 2. On the Osteology of some of the Loricati. With 5 plates. By J. E. Gutherlet. 50 cts.  
 No. 3. Studies on Gregarines, including twenty-one new species and a synopsis of the Eugregarine records from the Myriapoda, Coleoptera, and Orthoptera of the world. With 15 plates. By Minnie E. Watson. \$2.00.  
 No. 4. The Genus *Meliola* in Porto Rico. With 5 plates. By Frank L. Stevens. 75 cts.

#### Vol. III

- No. 1. Studies on the factors controlling the rate of regeneration. By Charles Zeleny. \$1.25.  
 No. 2. The head-capsule and mouth-parts of Diptera. With 25 plates. By Alvah Peterson. \$2.00.  
 No. 3. Studies on North American Polystomidae, Aspidogastridae, and Paramphistomidae. With 11 plates. By Horace W. Stunkard. \$1.25.  
 No. 4. Color and color-pattern mechanism of Tiger Beetles. With 29 black and 3 colored plates. By Victor E. Shelford. \$2.00.

#### Vol. IV

- No. 1. Life history studies on Montana Trematodes. By E. C. Faust. With 9 plates. \$2.00.  
 No. 2. The Goldfish as a test animal in the study of toxicity. By E. B. Powers. \$1.00.  
 No. 3. Morphology and biology of some Turbellaria from the Mississippi basin. With 3 plates. By Ruth Higley. \$1.25.  
 No. 4. North American pseudophyllidean Cestodes from fishes. With 13 plates. By A. R. Cooper. \$2.00

#### Vol. V

- No. 1. The Skull of *Amiurus*. With 8 plates. By J. E. Kindred. (in press)

### UNIVERSITY OF ILLINOIS STUDIES IN LANGUAGE AND LITERATURE

The Studies in Language and Literature are designed to include monographs in general linguistics and comparative literature; the classical languages and Sanskrit; the Romance languages; and English, the Scandinavian, and other Germanic languages. The title of the series will be so construed as to admit the publication of such researches in the history of culture as may throw light on the processes of language and the interpretation of literature. This series is published quarterly; the annual subscription price is three dollars.

#### Vol. I

- Nos. 1 and 2. The phonology of the dialect of Aurland, Norway. By G. T. Flom. \$1.25.  
 Nos. 3 and 4. Studies in the Milton tradition. By John Walter Good. \$1.75.

Entered as second-class matter July 27, 1915, at the post-office at Urbana, Illinois, under the Act of August 24, 1912. Acceptance for mailing at the special rate of postage provided for in section 1103, Act of October 3, 1917, authorized July 31, 1918

UNIVERSITY OF ILLINOIS STUDIES IN LANGUAGE AND  
LITERATURE.—Continued.

Vol. II

- No. 1. Thomas Warton: a biographical and critical study. By Clarissa Rinaker. \$1.00.  
No. 2. Illustrations of medieval romance on tiles from Chertsey Abbey. By Roger Sherman Loomis. 75 cts.  
No. 3. Joseph Ritson: a critical biography. By Henry Alfred Burd. \$1.15.  
No. 4. Miscellanea Hibernica. By Kuno Meyer. \$1.00.

Vol. III

- No. 1. The *Ad Deum Vadit* of Jean Gerson. By David Hobart Carnahan. \$1.75.  
No. 2. Tagalog Texts with grammatical analysis. Part I. Texts and translation. By Leonard Bloomfield. \$1.50.  
No. 3. The same. Part II. Grammatical analysis. By Leonard Bloomfield. \$3.00.  
No. 4. The same. Part III. List of formations and glossary. By Leonard Bloomfield. \$1.50.

Vol. IV

- No. 1. Madame de Staël's literary reputation in England. By Robert C Whitford. 75 cts.  
No. 2. Index verborum quae in Senecae fabulis necnon in Octavia Praetexta reperiuntur a Guiljelmo Abbott Oldfather, Arthuro Stanley Pease, Howardo Vernon Canter confectus. (In press.)

UNIVERSITY OF ILLINOIS STUDIES IN THE SOCIAL SCIENCES

The University of Illinois Studies in the Social Sciences are designed to afford a means of publishing monographs prepared by graduate students or members of the faculty in the departments of history, economics, political science, and sociology. Each volume will consist of about 600 printed pages annually. The subscription price is three dollars a year.

Vol. I

- Nos. 1 and 2. Financial history of Ohio. By E. L. Bogart. \$1.80.  
No. 3. Sources of municipal revenues in Illinois. By L. D. Upson. *Out of print.*  
No. 4. Friedrich Gentz: an opponent of the French revolution and Napoleon. By P. F. Reiff. 80 cts.

Vol. II

- No. 1. Taxation of corporations in Illinois, other than railroads, since 1872. By J. R. Moore. 55 cts.  
Nos. 2 and 3. The West in the diplomatic negotiations of the American Revolution. By P. C. Phillips. \$1.25.  
No. 4. The development of banking in Illinois, 1817-1863. By G. W. Dowrie. 90 cts.

Vol. III

- Nos. 1 and 2. The history of the general property tax in Illinois. By R. M. Haig. \$1.25.  
No. 3. The Scandinavian element in the United States. By K. C. Babcock. *Out of print.*  
No. 4. Church and state in Massachusetts, 1691-1740. By Susan M. Reed. \$1.05.

Vol. IV

- Nos. 1. The Illinois Whigs before 1846. By C. M. Thompson. 95 cts.  
No. 2. The defeat of Varus and the German frontier policy of Augustus. By W. A. Oldfather and H. V. Canter. 75 cts.  
Nos. 3 and 4. The history of the Illinois Central railway to 1870. By H. G. Brownson. \$1.25.

Vol. V

- No. 1. Enforcement of international law by municipal law in the United States. By Phillip Quincy Wright. \$1.25.  
No. 2. The life of Jesse W. Fell. By Frances M. Morehouse. 60 cts.  
No. 3. Land tenure in the United States with special reverence to Illinois. By Charles L. Stewart. 75 cts.  
No. 4. Mine taxation in the United States. By L. E. Young. \$1.50.

UNIVERSITY OF ILLINOIS STUDIES IN THE SOCIAL SCIENCES.—Continued

Vol. VI

- Nos. 1 and 2. The veto power of the Governor of Illinois. By N. H. Debel. \$1.00.  
No. 3. Wage bargaining on the vessels of the Great Lakes. By H. E. Hoagland. \$1.50.  
No. 4. The household of a Tudor nobleman. By P. V. B. Jones. \$1.50.

UNIVERSITY STUDIES

GENERAL SERIES, Vol. I, II, AND III

Partly out of print. A detailed list of these numbers will be sent on request.

Vol. IV

- No. 1. The origin of the land grant of 1862 (the so-called Morrill act) and some account of its author, Jonathan B. Turner. By E. J. James. Cloth \$1.35; paper 75 cts.  
No. 2. Fragment RA.58C of Konongs Skuggsja, from an old Norwegian parchment codex of the XIIIth century, with heliotype copy and a study of the paleography and the language. By G. T. Flom. \$1.25.  
No. 3. Michel-Jean Sedaine: Le philosophe sans le savoir. Variorum critical edition, based upon the second Paris edition of 1766 and its appendix with an introduction treating of all known editions and translations. By T. E. Oliver, \$1.75.

PUBLICATIONS OF THE UNIVERSITY OF ILLINOIS

Following is a partial list of the publications issued at the University:

1. THE UNIVERSITY OF ILLINOIS STUDIES IN LANGUAGE AND LITERATURE. Published quarterly. Three dollars a year.
2. THE UNIVERSITY OF ILLINOIS STUDIES IN THE SOCIAL SCIENCES. Monographs in history, economics, political science, and sociology. Quarterly. Three dollars a year.
3. THE ILLINOIS BIOLOGICAL MONOGRAPHS. Quarterly. Three dollars a year.
4. THE UNIVERSITY STUDIES. A series of monographs on miscellaneous subjects.
5. THE JOURNAL OF ENGLISH AND GERMANIC PHILOLOGY. Quarterly. Three dollars a year.

For any of the above address 156 Administration Building, Urbana, Illinois.

6. THE BULLETIN OF THE ENGINEERING EXPERIMENT STATION. Reports of the research work in the Engineering Experiment Station. Address Director of Engineering Experiment Station, University of Illinois.
7. THE BULLETIN OF THE AGRICULTURAL EXPERIMENT STATION. Address Director of Agricultural Experiment Station, University of Illinois.
8. THE BULLETIN OF THE STATE LABORATORY OF NATURAL HISTORY. Address Director of State Laboratory of Natural History, University of Illinois.
9. THE BULLETIN OF THE STATE GEOLOGICAL SURVEY. Address Director of State Geological Survey, University of Illinois.
10. THE BULLETIN OF THE STATE WATER SURVEY. Address Director of State Water Survey, University of Illinois.
11. THE REPORT OF THE STATE ENTOMOLOGIST. Address State Entomologist, University of Illinois.
12. THE BULLETIN OF THE ILLINOIS ASSOCIATION OF TEACHERS OF ENGLISH. Address 301 University Hall, University of Illinois.
13. THE BULLETIN OF THE SCHOOL OF EDUCATION. Address 203 University Hall, University of Illinois.
14. THE LAW BULLETIN. Address 207 Law Building, University of Illinois.
15. The general series, containing the University catalog and circulars of special departments. Address The Registrar, University of Illinois.

## INTRODUCTION

The study of the development of the teleost skull has been confined for the most part to isolated stages and there have been very few papers dealing with the changes which take place in any one species. Parker's (1872) work on the development of the cranium of *Salmo* has remained the standard and has been supplemented by Gaupp (1902) and Schleip (1903). Winslow (1897) describes the chondrocranium of the trout, Ryder (1886) and Pollard (1895) the chondrocrania of some of the Siluroids, but none of these attempted to trace the formation of the bones and their relation to the cartilage, in the same way that Parker did. Swinnerton (1902) has described several stages in the development of the skull of *Gasterosteus*.

The skull of the adult teleost has been widely studied in a topographical way, but very few authors have analyzed the bones in terms of their developmental relations, so that a wide field is open for this line of investigation. Gouan (1770) gives a simple account of the bones of the cranium and naively states that although there are many bones in the cranium of the young fish, these fuse into several large bones in the adult, as in man. Many of the names in use in the terminology of the present time have come directly from Cuvier, but others have been introduced into the literature principally by Owen (1848), Huxley (1864), and Parker (1872). Except for a few scattered references to the cranium of *Silurus glanis*, *Clarias*, *Auchenaspis*, and the incomplete description of the cranium of the adult *Amiurus* by McMurrich (1884), the skull of the Siluroids has been neglected.

This study of *Amiurus* has been undertaken because of the low organization of the Siluroids and the primitive relation of certain parts of the skull. Many points of relationship with the ganoids have been found and a sounder basis for grouping the Siluroids with the Characinidae and the Cyprinidae, has been developed. Very early stages of the skull were not procurable, so that the following account is based upon the 8, 10, 20, 32 and 60 mm. stages, though earlier stages than the earliest of these may be described in a later paper. Most of the material was obtained from Wisconsin, though the 32 mm. stage was supplied by Professor J. S. Kingsley under whose direction the work was completed, and whom I take this opportunity to thank for the many helpful suggestions and facilities placed at my disposal. The adult specimens, obtained through the generosity of the Illinois Natural History Survey, came from the Illinois River. ✓

### THE CHONDROCRANIUM OF THE 10 MM. LARVA

The description of the early chondrocranium of *Amiurus* is based upon the study of a group of specimens from 8 to 10 mm. in length. Earlier stages than the 8 mm. larva were not procurable. From one series of transverse sections of a 10 mm. larva of *A. nebulosus* (catus), a wax model of the entire cranium and the visceral arches was made by Born's method of reconstruction. The description of this is supplemented by a careful microscopical examination of several other specimens.

The cranium is elongate and not as depressed as it is in the adult animal. There is no roof of cartilage or of bone above the brain at this stage, although a transverse bar between the alisphenoid cartilages of the two sides divides the large space into an anterior and a posterior fontanelle (Fig. 2). The anterior of these is the smaller and is limited to the region above the forebrain and the olfactory region. The posterior fontanelle is very large and extends posteriorly between the dorsal margins of the otic capsules, its posterior margin is formed by the occipital arch.

The floor of the cranium is fenestrated by the large oval fenestra hypophyseos (*f.h.*), which extends from the anterior end of the parachordal plate (*pch*) to the posterior end of the ethmoid plate (*eth*), the trabeculae cranii (*tr*) forming its lateral margins. The parachordal plate is solid posteriorly and is grooved for the reception of the sacculi of the inner ears. On either side and above the parachordal plate the otic capsules are situated and the only foramina in the wall of the cranium in this region are those for the passage to the exterior of the glossopharyngeal (Fig. 1, IX) and vagus nerves (X), nothing comparable to the posterior basicranial fenestra and the basicapsular fenestrae of *Salmo* (Parker, 1872; Gaupp, 1906) being observed. The cavum of the labyrinth opens widely into the cavum cranii. The alisphenoid cartilage, extending dorsally and anteriorly from the anterior end of the otic capsule, forms the dorsal margin of a large foramen in the cranial wall, through which the optic, oculomotor, abducens, trigeminal and facialis nerves issue (Figs. 1, 2). The nerves penetrate the connective tissue membrane which extends across the fenestra from the alisphenoid cartilage to the trabecula cranii (Fig. 14). The detailed descriptions of the various regions of the cranium and the comparisons with the chondrocranial parts of other forms follows.

*The ethmoid region.* At the 10 mm. stage in the development of the ethmoid region, the dorsal surface of the cartilage forms a trough, the sides of which are formed by dorsal projections near the lateral edges of the plate; the floor is formed by the ethmoid plate itself (Fig. 2). The olfactory lobes

lie in this trough and are roofed by membrane which extends between the two lateral projections and is attached dorsally to the integument. The olfactory foramen, which is very large at this stage, occupies the anterior half of the lateral wall of this region and the olfactory lobe protrudes through this foramen (Fig. 1). A short olfactory tract extends from the lateral part of the lobe to the olfactory bulb which lies just lateral to it. The ethmoid plate extends laterally beyond these walls (Fig. 30) and forms the floor, called by Gaupp (1906) the *solum nasi* in *Salmo*, of the nasal fossa of each side (Fig. 2). The anterior end of the plate projects as two massive cartilaginous processes, the ethmoid cornua (Fig. 2). Just behind these a transverse ridge in the middle of the plate forms the anterior end of the *cavum cranii* and marks the anterior extent of the olfactory lobes. The ventral surface of the ethmoid plate is slightly concave (Fig. 30). At the posterior end of the ethmoid region, the anterior ends of the fused trabeculae and alisphenoid cartilages fuse with the side walls and floor of the trough and the floor forms the anterior margin of the fenestra hypophyseos (Fig. 2). Each lateral wall of the ethmoid region is produced laterally into an ectethmoid process, which projects abruptly from the external face of the cranial wall and the ventral face of which forms the articular surface for the palatine cartilage (Fig. 1). The anterior face of the process is concave near its ventral margin: the ophthalmic superficialis ramus of the trigeminus passes obliquely through the dorsal margin. The posterior face of the process is fused medially to the anterior dorsal margin of the alisphenoid cartilage. The ventral part of this fused region is separated from the trabecula by a small foramen, behind the ectethmoid process, the orbital foramen (Fig. 1). This foramen is the posterior limit of the ethmoid region or wall. As yet there is no internasal septum between the olfactory lobes of the two sides. The oblique eye muscles have no relation to the ventral surface of the ethmoid plate as they have in *Salmo* (Gaupp, 1906), but are attached to the ventral margin of the orbital foramen posterior to the ectethmoid process.

Sagemehl (1885) discussed the morphology and development of the olfactory region in the different families of teleosts. He recognized three different degrees of relationship between the olfactory organ, the bulbous olfactorius, and the brain. In the first and most primitive relation which he described as the Cyclostome type, the bulbous lies between the brain and the organ, within the *cavum cranii*, closely fused to each. With subsequent development a long tractus olfactorius is spun out between them, and the bulbous remains applied to the olfactory organ. He called this the Selachian type, as it is most common in this group. It is also found in the Cyprinoids, Siluroids, Mormyrids, and Gadids among the teleosts. In these families the tractus always lies within a canal directly continuous with the *cavum cranii*.

In other teleost families, as represented by *Salmo*, a membranous inter-orbital septum is developed between the orbits, on the dorsal surface of the

trabecula communis. This septum, by growth backward and dorsally, limits the anterior extent of the cavum cranii. The bulbus olfactorius, which in the larva of one of these forms, has the primitive cyclostome relation, is carried posteriorly by the interorbital septum, so that it becomes enclosed within the cavum cranii. The bulbus retains its connexion with the olfactory organ by a long slender olfactory nerve which passes unenclosed across the orbit between the anterior end of the cavum wall and the ectethmoid process. Sagemehl recognizes this condition as the teleost type of olfactory development. It is also interesting to note that in the Characinidae (Sagemehl 1885), *Citharinus* is very close to the selachian type and *Macrodon* has the teleostean relation of parts. Other members of this family present greater or lesser degrees of relationship to the two types. The olfactory region at this stage of development in *Amiurus*, according to this view, has just reached the cyclostome stage. ✓

*The orbital region.* Each lateral wall in the orbital region of the 10 mm. *Amiurus* is formed by a ventral trabecular and a dorsal alisphenoid cartilage, between which, the optic, oculomotor, most of the trigeminal, the abducens and the facialis nerves pass outward (Figs. 1, 2). In front of the opticus these two cartilages meet and form a solid wall for a short distance, its continuity being broken by the orbital foramen, dorsal to which the alisphenoid is fused to the posterior face of the ectethmoid process. Posteriorly the alisphenoid cartilage is fused to the anterior face of the otic capsule. A connective tissue membranous wall connects the ventral margin of the alisphenoid cartilage with that of the trabecula and it is through this membrane that the above mentioned nerves pass (Fig. 14).

The ramus oticus of the facialis nerve passes ventro-dorsally through the alisphenoid cartilage, just anterior to its union with the otic capsule. At about the middle of the cartilage are two small foramina, the more ventral for the ramus ophthalmicus superficialis of the trigeminus and the more dorsal for the ophthalmicus superficialis of the facialis (Figs. 1, 2). After its exit from the cranium and its passage through the orbit, the ophthalmic branch of the trigeminus passes through the orbitonasal foramen of the ectethmoid process, mentioned above, while the ophthalmic branch of the facialis passes around the lateral margin of the process.

A cartilage bar, the epiphysial bar, described by Sagemehl (1885) in the adult Characinidae and Cyprinidae, and by Pollard (1895) in the Siluridae, extends across the dorsal surface of the forebrain just posterior to the ectethmoid processes and is fused at each end to the anterior dorsal ends of the alisphenoid cartilages. There is no other trace of a cranial roof in this region at this stage.

The alisphenoid cartilage was described by Sewertzoff (1897) in the larval *Acanthias* as a large cartilage lying lateral to the fore- and mid-brains and connected secondarily with the anterior parachordalia. Later it fuses behind with

the anterior margin of the otic capsule and below with the posterior end of the trabeculae cranii thus enclosing the optic, oculomotor, trigeminus and facialis nerves. It grows anteriorly to the ectethmoid process, an independent cartilage, and fuses with it. Dorso-medially it grows toward the middle line and unites with its fellow of the opposite side to form the solid cranial roof. Except for its ventro-posterior relations, the alisphenoid of *Acanthias* can be compared to that of *Amiurus*. In both, these cartilages form the anterior and dorsal margins of the foramina for the nerves mentioned above, and extend across the dorsal part of the orbit. There is no cartilaginous roof in the chondrocranium of *Amiurus* with the exception of the epiphysial bar, which may be a remnant of such a condition. The notch at the anterior margin of the optic fenestra of *Acanthias* is suggestive of the orbital foramen of *Amiurus*.

Parker (1882) recognized three cartilaginous parts in the lateral wall of the orbital region of the chondrocranium of *Acipenser ruthenus*: a posterior alisphenoidal part, lateral to the parachordal plate; an anterior orbitosphenoidal part; and a dorsal supraorbital part, which fuses with its fellow of the opposite side to form the cranial roof. The orbitosphenoidal part is pierced by the optic nerve and the alisphenoidal part by the trigeminus and the facialis. This is more like the adult *Acanthias* cranium than it is like the cranium of the developing *Amiurus*.

In the chondrocranium of *Lepidosteus osseus* (Parker, 1882), the alisphenoid cartilage curves anteriorly above the nerves, from the anterior edge of the otic capsules. It is a thin flat bar and forms the lateral margin of the almost circular fontanelle in the cranial roof. Ventro-anteriorly it unites with the anterior ends of the trabeculae at the anterior end of the orbit, as in *Amiurus*. Medially and anteriorly it fuses with its fellow, above the fore-brain, forming a solid cartilaginous tegmen cranii, the remnant of which as above, may be represented by the epiphysial bar of *Amiurus*.

Concerning this region in the *Polypterus* chondrocranium, Budgett (1900) says: "The lateral walls of the cranium extend forward from the auditory region on either side of the alisphenoid region as continuous vertical plates of cartilage, somewhat dumb-bell shaped in section and perforated by foramina for the III, V, and VII nerves in the thinner middle portion. In the sphenethmoid region there is a large lateral fontanelle closed only by membrane through which passes the optic nerve, while above and below this membranous portion there pass the thickened upper and lower cartilaginous borders of the cranial wall, connecting on either side the ethmoid region with the posterior region of the cranium."

Dorsally the alisphenoid cartilages of the two sides in *Polypterus* are connected with each other by a transverse cartilaginous bridge, which is placed further back in the roof than the epiphysial bar in the cranium of *Amiurus*. The general relations of the alisphenoid cartilage to the cranial nerves in this region are much the same as in the developing *Acanthias*, and are closer to

that condition than to the condition found in the chondrocranium of *Amiurus*. The epiphysial bar, which is found again among the Teleosts in *Gasterosteus* ✓✓ (Swinnerton 1902), the Characinidae (Sagemehl 1885), the Cyprinidae (Sagemehl 1891) and other Siluridae (Pollard 1895), is the striking feature of a comparison between these two forms, as *Polypterus* is specialized in so many other features, that it differs from even the majority of the ganoids and has been mentioned as representing the ancestral stage of the Stegocephali.

In *Gymnarchus niloticus* (Assheton, 1907) the early chondrocranium of which has been very briefly described from Budgett's collections and notes, there is a long slit-like foramen in the wall of the orbit just anterior to the otic capsule and a smaller anterior foramen separated from this for the passage of the opticus. There is also a transverse bar similar to the epiphysial bar of *Amiurus* and *Polypterus*, connected however with the anterior ethmoidal roof by a median longitudinal bar of cartilage, which divides the anterior fontanelle into two parts. This may be the representative of a group in which the reduction from the solid cartilaginous roof of the lower ganoids is taking place, a continuation of which would produce the condition found in *Polypterus* and *Amiurus*.

In *Salmo salar* (Parker 1873; Gaupp 1906) a cartilaginous bar extends on each side of the cranium above the orbit, from the anterior end of the otic capsule to the posterior margin of the tegmen cranii, which extends back as far as the middle of the orbit. Posteriorly, between this bar and the otic capsule, the branches of the facialis and the jugular vein pass through separate foramina in the cartilage. The bar itself (called by Gaupp the *taenia marginalis*) extends anteriorly above the trigeminus and does not enclose any of its branches. Here, as in *Amiurus*, the large fenestra left in the wall between this cartilage and the trabeculae cranii is closed by membrane, through which the nerves issuing from the cranium pass. In *Amiurus*, as we have seen, both the fifth and seventh nerves issue through this membrane and with them the external carotid. In *Salmo*, as in *Acanthias*, these two nerves are separated from each other by a bar of cartilage, thus showing a nearer degree of relationship to the Selachian than to the Siluroid condition. The closer resemblance of *Salmo* to *Acanthias* is again evidenced by the presence of a well-developed tegmen cranii, not found in *Amiurus*.

In *Ceratodus* and the Urodeles the alisphenoid cartilage is fused ventrally ✓ with the trabecula during the first stages of development and later unites with the ethmoid and otic regions. As in the Ganoids and Teleosts, its anterior ✓ end and the trabecula enclose the optic nerve. Since the posterior ends of these cartilages enclose the trigeminus and the facialis, there is no question as to their homology with the alisphenoid and trabecular cartilages of these groups. Gaupp (1906) calls the former the *crista trabeculae*, thus adding to the confusion of names.

This same author claims that the cartilaginous bar, which I, following Sewertzoff, have called the alisphenoid cartilage, is not homologous with the alisphenoid cartilage of the Mammalia and therefore cannot be so named. He says that the ala temporalis in the mammalian cranium is a new formation, homologous with the process basiptyergoideus of the Lacertilian cranium, which arises from the procartilage cells around the anterior end of the palatopterygoid cartilage.

On comparison with the alisphenoid of mammals this homology falls to the ground if the relations of nerve and cartilage are used as the criteria for homologies of the chondrocranial parts. Throughout all of the lower Gnathostome groups the posterior end of this cartilage is connected with the development of the foramina for the passage of the branches of the trigeminus, but when such a cartilage appears in the mammals, the above associations are discounted and the cartilage is compared to an outside formation. In denying the homology, Gaupp takes this question into consideration, but maintains that the nerve relations are secondary and that nerves go through the ala temporalis because it replaces the original wall of this region. Assuming this to be the case, he states that anybody who relies upon the passage of nerves for their criteria of homology of cartilaginous parts is sure to err (1902). It is a settled fact, however, that ~~are~~ nerves constant throughout the vertebrate series and that they precede the cartilage in both ontogeny and phylogeny. Therefore, any homology which is made with these as a basis is sure to have a landmark which varies less than the parts of any other organic system, such as the blood vessels or muscles.

The trabeculae cranii are flat and acute on both inner and outer edges, becoming narrower anteriorly before uniting with the alisphenoid cartilages. Their posterior ends are fused with the anterior parachordalia and with them form the lateral margins of the fenestra hypophyseos and the fenestra basicranii anterior (Figs. 2, 14). The anterior ends are fused to each other median to their union with the alisphenoid cartilages and form the posterior margin of the ethmoid plate which has been discussed. There is no trabecula communis such as occurs in *Salmo*, the cranium being distinctly platybasic. An internal carotid artery approaches the trabecula of its side ventrally, and enters the cranial cavity through the inner edge in about the middle region of the orbit (Fig. 2), and proceeds anteriorly in the membranous wall of the orbit. Each artery sends a branch along the dorsal surface of the optic nerve and then unites lateral to the cerebral hemispheres with an internal branch from the external carotid.

The rectus eye muscles and a ligament to the pterygoid cartilage are attached to the lateral surface of each trabecula in the posterior part of the orbit. There is no trace of a myodome in this or the later stages. The oblique eye muscles are inserted on the trabeculae below the orbital foramen.

The fenestra hypophyseos and the fenestra basicranii anterior are closed by a sheet of fibrous connective tissue which stretches between the trabeculae (Fig. 14) and extends anteriorly below the ethmoid plate and posteriorly below the parachordal plate. It is not intimately connected with the cartilage of any of these parts.

In a 19 mm. larva of *Amia*, the rectus eye muscles are inserted in a space between the brain and the trabeculae, including some connective tissue with them. In the adult *Amia* in this region there is a canal separated from the cavum cranii by the prootic ossification. The trabeculae are wider in *Amia* than they are in *Amiurus* and form a trabecula communis before fusing with the ethmoid plate. In *Amia* each internal carotid artery passes through the trabecula on its medial side. The artery gives off a branch above the optic nerve in *Amia* as it does in *Amiurus*. The fenestra hypophyseos in *Amia* is even smaller than in the known higher teleosts. In the cranial wall, anterior to the otic capsule, the fifth and seventh nerves are separated by a bar of cartilage between the trabecula and the otic capsule, as in the Selachians and the Salmonidae, differing in this respect from *Amiurus*.

The oblique eye muscles in a 19 mm. *Amia* are inserted in a foramen in the wall of the cranium between the ectethmoid process and the optic foramen, comparable to the orbital foramen of *Amiurus*. In *Amia* this foramen continues anteriorly with a groove on the dorso-lateral surface of the ethmoid plate. Beyond the eye-muscle insertion, the olfactory tractus continues along the anterior part of the same groove. In *Amiurus* this groove is lacking and the eye muscles do not enter the foramen. There is, however, a concavity on the anterior face of the ectethmoid process which, if continued through to the posterior, would end at the anterior margin of the orbital foramen and may have some significance in comparisons with the anterior continuation of the foramen in *Amia*. The cartilage of the ethmoid floor in this region between the anterior parts of the orbits, is thicker in *Amia* than it is in *Amiurus*.

In the *Acanthias* larva (Sewertzoff, 1897), the trabeculae develop as paired independent cartilages at right angles and ventral to the anterior ends of the parachordals, eventually becoming fused with their ventral faces. They grow forward on either side of the hypophysial region of the brain and fuse anteriorly as a trabecula communis plate. As the flexure of the neural parts disappears, the trabeculae become horizontal in position, except in that immediate region where they are attached to the parachordal plate. Unlike the trabeculae in *Amiurus*, the Selachian trabeculae later form a solid floor in the cranium. The cartilaginous connexion between the alisphenoid and trabecular cartilages is far more extensive in the later *Acanthias* than it ever is in *Amiurus*. The condition of the cranial floor of *Acipenser* (Parker, 1882a), is the same as that of *Acanthias*, although the fenestra hypophyseos may persist for a longer time. In the early *Lepidosteus* cranium (Parker, 1882b) there is a large fenestra hypophyseos which later becomes closed by the growth medially of

the trabeculae. There is a large fenestra hypophyseos in the chondrocranium of the larval *Polypterus* (Budgett, 1907) which, from its ellipsoidal shape, is comparable to that of *Amiurus*. In none of these, however, have the relation of the internal carotid and trabecula been brought out. In all cases the nerves of the cranial series, from the second to the seventh, issue from the cranium above the trabeculae.

In *Salmo* (Parker, 1872; Gaupp, 1906) the trabeculae unite immediately anterior to the hypophysial region to form an elongated anteriorly extending trabecula communis, on the dorsal surface of which the membranous interorbital septum rises. The relation of the trabecula to the nerves is typical, but the trabeculae do not meet the alisphenoid cartilages in the medial wall of the orbit as in the Selachians, Ganoids, and *Amiurus*. Further comparisons of the relations of the trabeculae in other groups than the fishes are made by Parker and Bettany (1877), and Gaupp (1906).

*The otic region.* The otic capsules at this stage are two large cartilaginous masses forming the sides of the posterior region of the cavum cranii (Figs. 1, 2). Ventrally, they are fused with the basal plate of the posterior cranial floor, from the posterior ends of the trabeculae to the occipital arch, and there is no gap (basicapsular fenestra, Parker, in *Salmo*) between each capsule and the basal plate. Posteriorly there is no line of division between the occipital arch and the posterior boundary of the otic capsules. Anteriorly the cartilage surrounding each auditory mass is confluent with the posterior end of the alisphenoid cartilage. The dorsal medial margins, at this stage, do not meet above the hind-brain to form a cartilaginous synotic tectum as is found in other teleosts (Fig. 2).

The vagus nerve passes obliquely between the otic capsule and the ventral end of the occipital arch, latero-dorsal to the parachordal plate. The glossopharyngeal nerve has a smaller and more anterior foramen in the floor of the otic capsule and is separated from the foramen of the vagus by a small bar of cartilage.

The cavum of the otic capsule is fully open to the cavum cranii, except at the extreme anterior end where there is a small medial wall, bounding the anterior part of the anterior semicircular canal. The cavum within the capsule is divided by three septa semicircularia into the cartilaginous labyrinth containing the membranous semicircular canals. The septum semicircularis anterior, as in the adult (Fig. 7), is a short bar of cartilage extending from the anterior wall of the capsule posteriorly to the midventral surface of the roof, parallel to the long axis of the body. From its dorsal connexion with the utriculus, the anterior membranous semicircular canal passes above this septum into the anterior part of the capsule. The septum semicircularis laterale is situated at right angles to the anterior septum between the roof and the floor of the capsule, but nearer to the posterior than to the anterior septum. The anterior end of

the membranous lateral semicircular canal and the ventral end of the anterior enter the cavum cranii anterior to this septum laterale. The posterior end of the membranous lateral semicircular canal and the ventral end of the posterior, enter posterior to it. The septum semicircularis posterius lies in about the same horizontal plane as the anterior and makes an angle of about 120 degrees with the ventral surface of the roof of the capsule. The posterior end of this septum is continued as a medial wall between the cavum of the posterior membranous semicircular canal and the cavum cranii. The dorsal end of this canal passes posteriorly above this septum. The fenestrae above both the anterior and posterior septa are much smaller than the fenestrae anterior and posterior to the lateral septum.

After leaving the ganglionic mass of the facialis, the ramus lateralis accessorius of this nerve proceeds dorsally and curves around the anterior end of the roof of the capsule and thence along the dorsal surface of the cartilage, above the occipital arch to the body musculature. In all this distance the nerve is unenclosed by cartilage, nor is there any indication of ossification around it. It is accompanied by a branch of the internal jugular which descends and fuses with the postcardinal vein in the region of the second neural arch.

The hyomandibular cartilage articulates with the external surface of the ventro-lateral wall of the anterior and lateral semicircular canals (Figs. 1, 2). This articulation extends from the ventro-anterior edge of the capsule just above the posterior margin of the foramen for the facialis nerve, posteriorly in an obliquely dorsal direction toward the lateral edge of the roof of the capsule. The articular surface is very small in comparison with the longitudinal extent of the capsule and at this stage there is no projecting shelf for this articulation. In a nine day *Ictalurus albidus* chondrocranium (Ryder, 1886), the hyomandibular articulation differs from that in *Amiurus*, the anterior end being more dorsal than the posterior and, in addition, the surface is smaller and is overlapped by a process from the anterior margin of the capsule, suggestive of the pterotic ridge of *Polypterus* (Budgett) in the same region. The hyomandibular articulation of other teleosts and some of the ganoids is in nearly the same plane and region as in *Amiurus*, this scheme of articulation appearing to be typical for these groups.

The otic capsule of the *Amiurus* type is apparently derived from a primitive condition represented by the Cyclostomes (Parker and Sewertzoff) and found in the larval *Acanthias* as well. In these forms the otic capsules are fused, ventrally, to the basal plate and the cavum of each communicates with the cavum cranii by a large foramen through which the seventh and eighth cranial nerves enter the capsule. The ninth and tenth nerves leave the cranium posterior to the capsule in the Cyclostomes, but are in the same relative position in the larval *Acanthias* as in *Amiurus*. In *Amiurus* (p. 13) these leave by separate foramina, the tenth between the otic capsule and the occipital arch, the ninth a little anterior. A description of the septa semicir-

cularia of the Cyclostomes is lacking, so a comparison with the inner surface of the capsules cannot be made. However the structure of the ears in these forms is so different from that of the Gnathostomes, that detailed comparisons would have little value here.

In the larval *Acanthias* the fenestra of communication between the cavum cranii and the cavum labyrinthii is as wide as it is in *Amiurus*, but a wall is beginning to grow from the line between otic capsule and basal plate, which will eventually separate the two cavi. Sagemehl, from his comparative morphological study of the crania of the teleosts, says that their condition in this region is derived from the constant fenestration of the foramen for the auditory nerve, rather than from the Cyclostome condition. The evidence given above of the presence of a wide fenestra in the larval *Acanthias* is against his view and in favor of the derivation of the condition in the teleosts from an ancestor with a wide fenestra.

The ninth and tenth nerves leave the cranium by separate foramina in *Acanthias* just as they do in *Amiurus*, as stated above. The synotic tectum in *Acanthias* is formed very early by the growth of the median margins of the otic capsules, a condition not reached by *Amiurus* until very late in the larval period and then only for a short distance anteriorly.

The relation of the capsules to the basal plate and to the cavum cranii of *Lepidosteus osseus* (Parker, 1882), is much the same as in *Amiurus* except for the large fenestra in the ventral floor of each capsule. There is no wall between the cavum cranii and that part of the capsule containing the inner ear. A detailed description of the septal relations is lacking.

Part for part, the otic capsule of the larval *Salmo* as described by Gaupp (1906) is nearer to the condition of *Amiurus* than any other that has as yet been described. Except for the precocity in the growth of *Amiurus* they can be said to be identical in all their relations, if the presence of the basicapsular fenestra in the floor of the capsule be left out of consideration. There is the same relation of cavum of the labyrinth to cavum cranii and the same number of septa semicircularia are present and have the same relation to the membranous labyrinth in both forms. The relations of the ninth and tenth nerves are homologous in both cases. Externally the hyomandibular articular surface is about in the same region in both. The synotic tectum of *Salmo* is very well developed as compared with that region of *Amiurus*. Except for the inclusion of the branches of the facialis between it and the alisphenoid cartilage in *Salmo*, the anterior margins of the capsules are homologous, although the processus postorbitalis is more pronounced in *Salmo* than in *Amiurus*. From these comparisons it may be observed that *Amiurus* has an otic capsule which, except for several minor differences, is typical of the teleostean condition.

*The parachordal region.* Authors describing the origin of the chondrocranium in the teleosts have remarked that the basal plate of the older larva

arises from paired cartilaginous masses lying lateral to the notochord. Stöhr (1882) differentiated each of these masses into an anterior and a posterior part, the anterior lying medial to the otic capsules, and the posterior behind the exit of the vagus nerve from the cranium. The parachordal masses, as these cartilages are called, eventually fuse, partially at least, with each other around the notochord, anteriorly with the posterior ends of the trabeculae, laterally with the otic capsules, and posteriorly form the base of the occipital region. Concerning the parachordals in a general way, Parker and Bettany (1877; p. 311) say: "When the parachordals unite in the region where the notochord still persists, it is by growth of the cartilage over and under it. The bridge beneath the notochord is very marked and becomes thick; the cartilage is thinner above, and often nonexistent for a long time, so that the notochord lies in a groove on the basilar plate constituted by the union of the parachordalia. In many cases where a basicranial fontanelle exists, the cartilages do not approach one another again, and the fontanelle is only closed by a bony growth. . . . The whole of the cranial notochord is gradually aborted in most instances, and its place is occupied by cartilage; but in various forms a remnant is left as a slender string, embedded in the basioccipital bone or cartilage."

In the chondrocranium of the 10 mm. *Amiurus*, the parachordalia have already passed through the early stages of development and are partially fused with each other, with the trabeculae, and the otic capsules, forming the base of the occipital region (Fig. 21).

Terry (1917) has recently worked over the literature on the parachordal region of the mammals and concludes that the parachordals may arise in three ways: from a hypochordal center of chondrification; from a pair of bilaterally placed masses; and by growth and fusion of the apposed ends of the lateral occipital arches. In the 10 mm. cat, the notochord enters the occipital region between two laterally lying parachordal cartilages, dorsal to a mesenchymal sheet which connects them. This sheet later becomes chondrified in connexion with the parachordals, forming thus an hypochordal bridge of cartilage. This agrees with the statement quoted from Parker and Bettany, but cannot be applied as a rule for the development of the basal plate of the teleost chondrocranium, as the condition in *Amiurus* shows.

The concavity marking the anterior extent of the notochord on the ventral surface of the plate is continued anteriorly beyond the tip of the notochord as far as the margin of the fenestra basicranii anterior. The anterior end of the notochord does not project into fenestra basicranii posterior, for such is absent in *Amiurus*. There is no fenestra between the parachordal and the otic capsule corresponding to the basicapsular fenestra of *Salmo*.

The sacculi of the inner ears have invaded the cartilage of the basal plate to such an extent that they have replaced most of it (Fig. 8). The grooves on the dorsal surface of the plate containing them extend from below the base

of the lateral septum semicircularis to the posterior end of the cranium, lateral to the notochord. The sacculi communicate with each other across the anterior ends of these grooves, above the tip of the notochord, by a transverse canal sinus impar (ductus endolymphaticus, Wright, 1884), from the posterior wall of which the sinus impar of the Weberian apparatus projects. This sinus impar lies along the mid-dorsal surface of the cavum floor and is separated from the laterally situated sacculi by a membranous V-shaped wall, the apex of which is attached to the dorsal surface of the notochord (Figs. 17, 21). It is separated from the cavum cranii by a membranous roof which continues laterally as the roof of the saccular recesses and is attached to the cranial wall at the junction of otic capsule and parachordal cartilages. Posteriorly, the membranous roof over the saccular cavities is replaced by cartilage which is continuous medially with the ventral walls of the cavum sinus imparis and laterally adjoins the otic capsule. The ventral floor of each recessus sacculi is very thin (Fig. 8), but the posterior wall which marks the posterior extent of the parachordal plate is thick dorso-ventrally (Fig. 21). The dorso-lateral surface of this posterior part of the parachordal plate is separated from the ventral end of the occipital arch posterior to the otic capsule (Fig. 17), and through this space the sinus impar communicates with the Weberian ossicles contained in the saccus paravertebralis. The first post-vagal nerve or hypoglossus passes out through this space, but does not touch the cartilage of the posterior end of the parachordal plate which has narrowed considerably in this region.

The relations of the inner ear to the cranial floor have been described by several investigators in those forms having a Weberian apparatus, but the descriptions have been confined to adult conditions. In a later paper, I hope to follow the developmental relations of the inner ear to the parachordals, if I am fortunate enough to obtain the proper stages.

There is no evidence of segmentation of the basal plate at this stage, such as is found at the posterior end of the parachordal plate of *Acanthias* (Sewertzoff, 1897). The distinct ridge of cartilage, called the 'Sattellehne,' is lacking in *Amiurus* because the trabeculae do not become attached to the ventral surface of the parachordalia, but lie in the same plane with them. Like the intercapsular floor of *Acanthias*, this region of *Amiurus* is solid, and, although in the early stages of *Acanthias* the notochord projects into the basicranial fenestra, it is later enclosed by cartilage as in *Amiurus*. The inner ear relations have nothing in common as regards the parachordal plate, because in the older *Acanthias* the cavum of the ear is shut off from the cavum cranii by a wall of cartilage.

As I was unable to find any statement concerning the later larval history of the parachordalia of *Amia*, I found it necessary to study a series of transverse sections through the head of a specimen 19 mm. long. I have referred

to the condition in the anterior region of the head of this same specimen earlier in this description.

The parachordalia do not extend beyond the anterior end of the notochord, but lie lateral to and separated from it by a space filled with a stroma of pro-cartilage cells. This space is comparable to the posterior basicranial fenestra which Gaupp has described for the 25 mm. *Salmo*, but which is lacking in the 10 mm. *Amiurus*. The parachordalia are triangular in cross-section and are fused latero-dorsally with the floor of the saccular cavity of the otic capsule. A sharp crest marks the line of division between the two, and from the dorsal edge of this crest a membrane extends to the roof of the cranium, separating the *cavum cranii* from the *cavum labyrinthii*. The sacculus lies on the capsular side of this membrane within the otic capsule, on a higher plane than the medial ends of the parachordals. As the parachordals extend posteriorly, they gradually come in contact with the lateral surfaces of the notochord, at first by a sharp edge which gradually becomes blunt and finally concave, as it comes into closer contact with the notochord. The parachordals of the two sides remain distinct from each other however, and I was unable to observe a region of fusion, either above or below the notochord. The glossopharyngeal nerve passes to the exterior through the *cavum labyrinthii* between the sacculus and the posterior semicircular canal. The passage of this nerve in *Amiurus* follows the same route between the sacculus and the semicircular canal, but the foramen lies between the dorso-lateral edge of the parachordal plate and the ventral margin of the capsule, rather than in the wall of the capsule proper as it does in *Amia*. The vagus nerve issues higher up in the wall than it does in *Amiurus* and instead of being ventral, is posterior to the otic capsule. The cartilage of the parachordals has a greater posterior extent in *Amia* than it has in *Amiurus*.

In a 25 mm. *Salmo*, as described by Gaupp, the parachordalia lie lateral to and close around the notochord, except at its anterior tip which projects freely into the posterior basicranial fenestra. This fenestra is cut off from the more anterior fenestra by a transverse bar of cartilage between the anterior ends of the parachordalia. The rectus eye muscles are inserted between the anterior ends of the parachordalia which form the lateral walls of an eye muscle canal in this region, the *cavum* of which is cut off from the *cavum cranii* by a membranous floor (See Gaupp, 1906, fig. 342). Commenting upon the parachordal relation Gaupp says: "Die Balkenenden verschmelzen mit den vorderen Parachordalia; die ursprüngliche Grenze liegt anfangs etwa in der Höhe der vordere Chordaspitze und entspricht dem (in dem Folge sich mehr verengernden) Uebergang der vorderen und hinteren basikranialen Fontanelle. Schliesslich tritt auch eine vordere und eine hintere Vereinigung zwischen dem Parachordale und dem inzwischen vergrossten periotische Knorpel ein."

As noted in the discussion of the otic region there is a fenestra between the parachordal cartilage and the otic capsule in *Salmo* which is not present in

Amiurus, and the ninth nerve issues through its posterior end. Whether the foramen for the passage of the ninth nerve in *Amia* and *Amiurus* is a remnant of this or not, it is hard to say without knowing the earlier history. The saccular relations are probably the same in *Salmo* as they are in *Amia*, as the *Siluridae* have a specialization not found in all of the teleosts, just as the eye muscle relations are peculiar in a certain large group with well-developed eyes.

The relations of the anterior end of the parachordals of *Amiurus* and of *Salmo* are homologous in that they lie between the otic capsules on either side of the notochord and are connected anteriorly with the trabeculae. Primitively they are alike, but specialization in one form in connexion with the ear and in the other with the eye have made detailed comparisons difficult.

*The occipital region.* As remarked above, the dorsal part of the occipital arch forms the posterior margin of the posterior fontanelle (Fig. 2). The occipital-otic capsule fusion takes place above the foramen for the vagus nerve, and behind it the ventral ends of the occipital arch are fused for a short distance to the parachordals (Fig. 21). Behind this region of fusion the anterior ends of the scaphoid processes project between the occipital arch and the parachordals. At this stage, the scaphoid process is a membranous plate connected posteriorly with the perichondrium of the cartilaginous scaphium (Fig. 13).

The first post-vagal nerve (Figs. 17, 35) leaves the vertebral canal between the anterior end of the scaphoid process and the ventral end of the occipital arch. This part of the arch is enclosed in a perichondrial ossification, even at this stage. The anterior margin of the foramen for the passage of the nerve is formed by the occipital arch-parachordal fusion. The cartilage of the parachordals does not extend posterior to this immediate region, and the diameter of the notochord is much larger than it was intercranially (compare Figs. 8 and 17). The elastica interna and externa are very distinct from each other in this part of the notochord.

On the median dorsal surface of the notochord there is a thickened mass of connective tissue, the endorhachis, which forms a floor for the support of the spinal cord (Fig. 13). This floor is supported laterally by connexion with the ventral ends of the occipital arch. In this manner the space between the occipital arch and the notochord is divided into three chambers, a dorsal unpaired one containing the spinal cord, and two lateroventral chambers, the lateral walls of which are formed by the scaphoid processes. The saccus paravertebralis lies external to each scaphoid process and contains the ossicles of the Weberian apparatus. The lateral chambers within the scaphoid processes are called the atria sinus imparis and are the posterior continuation of the sinus impar.

The scaphium (Fig. 13) at this stage, is a small piece of cartilage which articulates with the dorso-lateral surface of the notochord by a rounded end. It has all the appearances of a modified neurapophysis. Between its dorsal

end and the occipital arch there is a small triangular piece of cartilage, the claustrum of the Weberian apparatus. Sagemehl (1885) regarded this in the Characinidae as the first true neurapophysis, and maintained that the nerve which originally passed between the claustrum and the scaphium has been suppressed in those groups having a Weberian apparatus. The scaphium was homologized to the second neurapophysis.

The second pair of neurapophyses lie a short distance posterior to the scaphia and are separated from them by a pair of rather wide foramina through which the second pair of postvagal nerves issue (Figs. 12, 35). The ventral ends of these neurapophyses are concave and are closely applied to the notochord, in contradistinction to the rounded ends of the scaphia. Above the dorsal ends of this second pair of neurapophyses and the claustrum, the posterior end of the occipital arch has narrowed to a small process which is inserted into the anterior face of the third neural arch (Fig. 12). The posterior and ventral ends of this neural arch descend behind the second pair of neurapophyses, leaving a wide foramen in the wall on each side. The third postvagal nerve (Fig. 35) passes out through this foramen, nearer to the second neurapophysis than to the third.

Briefly, the skeletal and nerve elements alternate with each other in this region, just as they do farther back in the body (Fig. 35). None of the postvagal nerves are actually included within the cranium at this stage, as the dorsal and ventral parts of the occipital region have not as yet united posterior to the first pair. The dorsal surface of the occipital arch does not show any segmentation and ventrally it is continuous with the parachordalia posterior to the passage of the vagus nerve and the otic capsule (Fig. 21). The parachordal cartilages do not extend posteriorly beyond the passage of the first postvagal nerve and there is no cartilage lateral to the notochord until the ventral ends of the third neural arch are reached.

There are four distinct muscle segments between the posterior end of the otic capsule and the ventral end of the third neural arch on each side (Fig. 35). The more anterior are dorsal and oblique to the posterior, which extend in under their ventral ends (Figs. 12, 13). The first myotome is very short and projects into the shallow temporal fossa, lateral to the dorsal half of the occipital arch (Fig. 12). The second starts ventral to the first, and lateral to the passage of the first postvagal nerve. It is separated from the cartilage of the occipital arch by a wide space filled with loose connective tissue. The third myotome comes in below the second, lateral to and above the second postvagal nerve, and the fourth is lateral to the anterior projection of the neural arch of the third vertebra. Distinct myosepta are present between all of these segments.

All the postvagal nerves have both dorsal and ventral roots, but the first is the only one in which the ganglion of the dorsal root lies within the cavum spinalis. The ganglia of the others all lie external and lateral to the side walls of

the neural arches. All except the first have very well developed dorsalis and lateralis rami and usually an additional dorsal sensory ramus which proceeds dorsally to the epidermis (Fig. 12). The ramus lateralis of the first post-vagal nerve (Fig. 17) descends obliquely to the muscles in the ventral wall of the body between the parts of the shoulder girdle, and in this way is comparable to the somatic hypoglossal nerve of the higher groups. The first two muscle segments have no visible innervation. The third and fourth muscle segments are innervated by the distinct rami dorsales of the second and third nerves. The rami laterales of these two nerves descend, as did the ramus lateralis of the first nerve, to the musculature between and around the developing shoulder girdle.

The work of Gegenbaur (1887), Sagemehl (1884, 1885, 1891), Frieriep (1901), Stöhr (1882), Dohrn (1901), Sewertzoff (1895), Van Wijhe (1882), Fürbringer (1897), and others on the relation of the trunk and head in the occipital region has been reviewed by Gaupp (1906). He emphasizes the work of Fürbringer as a step in the right direction for the understanding of this question and I refer briefly to some of the points of interest in the researches of Fürbringer (1897).

According to this author, the crania of the Teleosts may be divided into two parts, and anterior paleocranium, ending with the vagus, and a part posterior to this, the neocranium. The neocranial condition arose from the assimilation of body segments and is represented in the occipital part of the cranium by skeletal segments and nerves. The primitive type of neocranium is termed the protometameric and is represented in the present day forms in the crania of the Selachians and the Amphibia. When more elements are assimilated the auximetameric condition is reached. This type of neocranium is found in the higher fishes and in the Amniotes. The distribution and occurrence of nerves posterior to the vagus are used by the author in his analysis of the types of neocrania in the different groups. The paleocranial nerves end with the vagus and the neocranial are those, which, before becoming included within the cranium, were of a free spinal type. These nerves so included are called the 'spino-occipital' nerves and are further divided into two categories; those enclosed in the protometameric neocranium are known as the 'occipitale' nerves and those in the auximetameric neocranium as the 'occipito-spinale' nerves. He explains the difference in number and appearance of these nerves in the different animal groups as the result of more or less assimilation of vertebrae and atrophy of somites. In his diagrammatic representations of the condition in the Selachians, the last 'occipitale' nerve is represented by the letter 'z' and the first of the 'occipito-spinale' nerves of the higher fishes and the Amniotes as 'a,' the homologue of the first free spinal nerve of the Selachians. Holocephala, Ganoids, Dipnoi, Teleosts, and Amniotes possess an occipital region of the auximetameric type. According to Fürbringer, different numbers of vertebrae and segments take part in the formation of this region,

so that the cranium does not end in the same place in all of these groups. The cranial-vertebral complex of the Amniotes includes three vertebrae and the hypoglossus nerve of this group is the result of the fusion of the three nerves corresponding to these three vertebrae. He says, that in a general way the auximetameric neocranium of the teleost agrees with the Amniotic condition.

The nerve formula for the occipital region of the Siluroids is b-0-4. According to this view, the first post-vagal nerve of *Amiurus* is an 'occipito-spinal' nerve and corresponds to the second free spinal nerve of the Selachians, which the Arabic numeral represents. Thus, there is one segment missing between the paleocranium of *Amiurus* and the auximetameric neocranium, and another between this and the first free spinal nerve. This method of reasoning is based on Sagemehl's hypothesis that in the Characinidae and the Siluridae, where the Weberian apparatus is developed, the claustrum represents the neurapophysis of a rudimentary vertebra, and that the nerve which originally came in between the claustrum and the scaphium is lost, together with the muscle segment. I do not regard the claustrum as a rudimentary vertebra, but as an intercalated cartilage, developed in connexion with the specialized Weberian ossicles. The scaphium may be the first true neurapophysis and a modified representative of this part of the first vertebra. I hope to get further evidence later for the exact somitic relations of these parts in younger larva than have yet been accessible. For the present I accept the hypothesis suggested by Kingsley (1910) concerning the relations of the occipital region in vertebrates, where he says: "In the vertebrates there is a continuous addition of new somites at the posterior end of the body as in the arthropods and annelids, implying the existence of the equivalent teloblasts at the posterior end. The assumption of budding zones at other points will explain other features noted. Such a zone in the occipital region will allow us to explain the difference in the number of cranial nerves in the Mammals and the Ichthyopsida and yet allow us to accept the homology of the occipital bone throughout the series. The additional nerves are thus to be regarded not as transferred from the neck, but as new or intercalated structures."

Reasoning on this basis, the first post-vagal nerve of *Amiurus* is a new, intercalated formation, possibly associated with the second somite. What part the first somite plays in the development of the occipital region I have not been able to ascertain, if we assume that the first dorsal muscle segment is that of the first metotic somite. In the larval *Salmo*, Miss Willcox found that there were five segments between the posterior end of the otic capsule and the first neurapophysis. Two of these disappear very early in development and have no trace of nerve connexions. The third has a rudimentary nerve which atrophies early. The next two nerves innervate the next two somites and issue from the cranium between the parachordals and the neurapophysis of the first vertebra. These are later enclosed in bone and leave the exoccipital through the same foramen as the hypoglossus. Fürbringer's formula for this

family is b-c-4, thus having one more element in the occipital region than is found in *Amiurus* and adding another vertebra to the cranium. The myotomes which disappeared in this case were those which took part in the formation of the protometameric neocranium, most traces of which have entirely disappeared in the teleosts (Fürbringer). But here, in the larval condition, there are more somites related to the occipital region than in *Amiurus* and yet the ultimate development is the occipital bones. If we assume with Fürbringer that there are more vertebrae in one case than in the other, our homologies are no longer such, but are analogies of structure without any natural relationship. Even within one family it would be possible to have an exoccipital vertebral articulation which was not constant, allowing for the attachment and detachment of vertebrae. If we assume that the first vertebra, however modified by specialization, remains constant throughout the series, and that the changes in the occipital region are brought about by intercalation of parts, then our homologies and our basis for natural relationship are maintained throughout all the groups.

Jordan (1893) in his work on the relation of the number of vertebrae and the distribution of fishes has shown conclusively that homologies cannot be based upon numerical sequence. He counted the number of vertebrae in closely related species of teleosts from northern and tropical waters and found that the tropical forms usually had the smaller number. The cranial nerves and bones were constant and yet there were cases of intercalation and excalation of the vertebrae.

Schauinsland (1906) has also shown that vertebrae can be intercalated, and that myotomes, nerves and blood vessels of the body cannot be serially homologized. There are various degrees of intercalation, from the presence of both arches, nerves and myotomes, to the absence of one or two of these elements. These facts give conclusive evidence that the nerves leaving the cranium posterior to the vagus cannot be serially homologized with free spinal nerves.

*The Maxillary region.* The premaxillary ossification, one of the few centers of ossification appearing in the cranium at this stage, is a thin horizontal osseous plate lying beneath the anterior end of the ethmoid cornu and extending posteriorly below the nasal organ forming the anlage of the nasal fossa floor (Fig. 18). It is connected with the ethmoid cartilage by a few strands of fibrous connective tissue, and with its fellow of the opposite side, but otherwise lies free in the mass of embryonic connective tissue in this region. Five or six developing teeth are attached to the ventral surface of the ossification.

Schleip (1903) says that the bone and the teeth arise separately in *Salmo* and fuse later. In the youngest *Amiurus* I have studied, the earlier stages have already been passed through, but some tooth germs lie below, unconnected with the posterior part of the ossification, and lend support to the view that *Amiurus* resembles *Salmo* in this respect. The ascending part of the ossifica-

tion in *Salmo* is lacking in *Amiurus*, but that which extends medially beneath the cranium corresponds in the two forms. I find no trace of a labial cartilage in *Amiurus*. In *Salmo* this lies between the cartilage of the ethmoid plate and the premaxillary ossification.

In the 10 mm. *Amiurus* the maxillary bone is represented by a small ossification lateral to the anterior end of the palatine cartilage (Fig. 30). The medial surface of this piece curves half way around the palatine cartilage and a small process projects laterally from its external surface, above the proximal end of the maxillary barbel. There are no teeth connected with the ossification. In *Salmo*, (Schleip, 1903) the maxillary ossification abuts against the palatal cartilage in the same region as in *Amiurus*, but teeth arising below it fuse with it later.

The palatine cartilage is a slender cylindrical bar lying lateral to and parallel with the ethmoid plate (Figs. 1, 2). It is not uniform in diameter, but tapers posteriorly. Its anterior end lies lateral to the nasal organ (Fig. 30) and posterior to it the medial surface is flattened for articulation with the lateral surface of the ectethmoid process. The posterior end of the palatine cartilage is connected with the anterior end of the pterygoid cartilage by a thin stroma of connective tissue cells, among which I was unable to find any cartilage cells. Muscle fibres extend to the dorsal and ventral surfaces of the posterior end of the cartilage from the margin of the ethmoid plate ventral to the orbital foramen.

The pterygoquadrate cartilage consists of an anterior, slender, flat pterygoid bar and a posterior thickened quadrate cartilage (Fig. 1). The pterygoid part extends anteriorly beneath the eye, parallel with the trabecula cranii and connected to it by a sheet of muscle fibres. It ends there and is connected with the posterior end of the palatine cartilage by the stroma of cells, mentioned above. Its posterior end descends obliquely toward the lower jaw and passes into the quadrate cartilage just dorsal to its articulation with Meckel's cartilage. The ventral anterior surface of the thickened quadrate cartilage is concave where it articulates with the dorsal surface of Meckel's cartilage; postero-dorsally the quadrate is indistinguishably fused with the hyomandibular cartilage.

The anterior end of the dorsal margin of the hyomandibular cartilage abuts against the latero-ventral surface of the posterior end of the alisphenoid cartilage (Fig. 1). From this point the articular surface for the hyomandibula extends obliquely dorso-posteriorly along the lateral wall of the otic capsule to a point external to the lateral semicircular canal. From this articulation the hyomandibular descends, as a thin vertical plate of cartilage, from the wall of the otic capsule behind the quadrate and is connected at its ventro-posterior end with hyoid cartilage by the interhyal. Its anterior ventral margin encloses the hyomandibularis branch of the facialis nerve. A cartilaginous process

for the support of the operculum projects from the posterior margin just below its articulation with the otic capsule.

The opercular bones are present at this stage as thin curved sheets of fibrous connective tissue posterior to and below the hyomandibular cartilage.

Meckel's cartilage has fused in front with its fellow of the opposite side forming a continuous lower jaw. The anterior part of the cartilage is slender and cylindrical, but posteriorly, just before articulation with the quadrate, there is a sharp process on the dorsal surface and the dorso-ventral diameter is greatly increased. A small piece of the cartilage extends posteriorly beyond the quadrate articular surface.

In Elasmobranchs (Holocephali excepted) the palatine cartilage is continuous with the pterygo-quadrate bar and abuts against the lateral surface of the trabecula by the palatal process. Its anterior extent is not as great as in *Amiurus* and it never comes in contact with the ectethmoid process, but fuses with the pars palatina of the opposite side forming a complete upper jaw. Since it is supported by the hyomandibula posteriorly and touches the cranium anteriorly, this type of jaw has been termed amphistylic. By dismemberment of the primitive upper jaw of the Elasmobranchs, the condition of *Amiurus* is brought about, and the palatine part of the arch is separated from the pterygo-quadrate part. Steps in this process occur in the ganoids (*Polypterus*) and in the teleosts (*Salmo*). In *Polypterus* (Budgett, 1900) the palatine is continuous with the pterygoquadrate part, as in the Elasmobranchs, but has an extent much greater anteriorly. There is no palatal process as in the latter group and the anterior end is attached to the ventral surface of the nasal capsule. In *Salmo* (Parker, 1872; Gaupp, 1906) the palatine cartilage is at first independent and secondarily fuses with the pterygoquadrate. It articulates with the ventral surface of the ectethmoid process, and, at a point anterior to this, with the ventral surface of the solum nasi. The part of the palatine which articulates with the ectethmoid process is club-shaped and larger than the more posterior part. Thus there are important differences in the shape of the cartilage and the manner of articulation when compared with *Amiurus*. The wider separation of the palatine cartilages and their articulation with the lateral surface of the ectethmoid process may be the result of the depression of the cranium. In *Gymnarchus* (Assheton, 1907) the palatine part of the palatopterygoid cartilage is fused with the ventral surface of the cranium, thus differing radically from the condition in *Salmo* and *Amiurus*.

In all of the forms referred to above, with the exception of *Amiurus*, the quadrate is a thickened mass of cartilage connected anteriorly with the pars palatina by the pterygoid cartilage and bearing on its ventral posterior part a surface for the articulation of Meckel's cartilage. The quadrate cartilage of *Amiurus* corresponds in its relations to those of the other forms, but it is fused dorso-posteriorly with the hyomandibula (Fig. 1). In *Polypterus*, the hyomandibular cartilage is dumbbell-shaped, one of its clubbed ends articulating

dorsally with the wall of the otic capsule and the other descending posterior to, but separate from, the quadrate cartilage. Unlike *Amia*, *Amiurus* and *Salmo*, it does not enclose the ramus hyomandibularis facialis. In *Amia* (Van Wijhe, 1882) the palatine and pterygoid cartilages are fused and have an articulation with the ventral surface of the ectethmoid process. In the latter forms the hyomandibular has a greater extent of articulation than in *Polypterus*, but the foramen for the hyomandibularis nerve is nearer the anterior edge of the cartilage in *Amiurus* than it is in *Salmo*. In the latter the quadrate lies much farther anterior to the bulk of the hyomandibula than it does in *Amiurus*, and a slender cartilaginous process descends below it from the anterior end of the hyomandibula. This is the symplectic element which is not independent in *Amiurus*, but is fused with the quadrate-hyomandibular mass of cartilage and may be the part which descends behind the quadrate and connects with the interhyal.

In all of these forms Meckel's cartilage has the same general shape and relations. The articular surface may be convex as in *Amiurus* or concave as in *Acanthias*. Usually a small bit of the posterior end projects beyond the quadrate. The coronoid process on the dorsal surface of the cartilage is well marked in *Polypterus*, but does not project as abruptly as in *Amiurus*. In *Salmo* the cartilage has practically the same size from anterior to posterior ends.

#### THE SKULL OF THE 32 MM. LARVA

The description given in the following section is based upon the study of the head region of 20 mm., 32 mm., and 60 mm. larvae. The first two stages were specimens of *Amiurus nebulosus* (catus), and the third of *A. melas*. A wax model of the cranium of the 32 mm. stage was made, as it gave all of the typical perichondrial and dermal ossifications at an intermediate stage in their development. One side of the model was left without osseous parts, to facilitate comparisons, as is commonly done in modelling of this kind. The 20 and 60 mm. stages were used to supplement this.

Nearly the whole roof of the cranium at this stage is covered by either perichondrial or dermal ossifications (Fig. 3). The former are derived from the ossification of the perichondrium of the chondrocranium and the latter from the ossification of connective tissue membrane external to it. Sometimes the two elements are intimately fused. Another type of bone development may be mentioned here, the ossification around a lateral line canal. The development of this type of bone has been worked out in detail by Platt (1893) and Klaatsch (1895).

The roof is no longer widely open as in the younger stage, but the fontanelles are limited to narrow slits, anteriorly between the frontals and posteriorly between the parietal part of the supraoccipital ossification (Fig. 3). The nasal region has an internasal septum which has grown up from the floor of the ethmoid plate, separating the olfactory lobes (Fig. 22).

In all parts of the cranium the cartilage is more massive and there are very few places where ossification has proceeded far enough to replace it entirely. The fenestra hypophyseos (Fig. 3) is narrower and is closed ventrally by the elongate parasphenoid ossification (Fig. 4). The cranium has grown 6 mm. in length since the 10 mm. stage, and is relatively much flatter. Detailed descriptions of the various cranial regions follow.

*The ethmoid region.* This part of the cranium differs considerably from the younger stage. The olfactory lobes are no longer in the very anterior region of the ethmoid plate, lateral and internal to the olfactory foramina (Fig. 30), but lie farther posteriorly, and a massive internasal septum has grown up between them (Fig. 22). The foramina, instead of lying in an antero-posterior plane parallel to the long axis of the body as in the 10 mm. stage, now lie almost at right angles to it (Fig. 3).

The ethmoid cornua, formerly wide blunt processes separated by a slight indentation, are now narrow and pointed, with a deep notch between them (Fig. 3). The floor of the nasal fossa (Fig. 22), the solum nasi of Gaupp, is wider and thicker than in the 10 mm. stage, although even now it does not extend as far laterally as the palatine cartilage. The ectethmoid process (Figs. 3, 4) described earlier as projecting from the cranial wall at the junction of the ethmoid and alisphenoid cartilages, forms an oblique ridge in the cranial wall above the orbital foramen (Fig. 39) and the anterior part of the orbit. The foramen orbitonasale is more posterior, evidence that the cranial parts anterior to it have elongated. The process in the dorsal part of the cranial wall has grown medially and has fused with the internasal septum to form a rudimentary tegmen cranii (Fig. 3).

The anterior margin of the fenestra hypophyseos, formed by the fusion of the anterior ends of the trabeculae, lies midventral to the optic foramina (Fig. 4), and farther posterior than in the younger stage. The orbital foramen is in approximately the same position as in the younger stage, but the posterior dorsal margin of the ectethmoid process now lies above it (Fig. 39). The foramen is limited by a perichondrial ossification between its ventral and dorsal margins, so that a small aperture is all that remains of the larger foramen of the 10 mm. stage. These ossifications are continuous anteriorly with the perichondrial ossifications on the posterior wall of the ectethmoid process.

A perichondrial ossification on the dorsal margin of the olfactory foramen encloses a branch of the internal carotid artery passing from the cranium to the nasal sac. The olfactory tract, from lobus to the olfactory foramen, is entirely enclosed within the cranium. The development from the condition in the younger stage, has kept the lobus close to the brain, while the anterior end of the cranium grew forward and pulled the olfactory organ with it, resulting in an elongate tractus olfactorius. This stage of the development of the olfactory relations is comparable to that of the Selachian type as has been pointed out in the Cyprinidae by Sagemehl (1891)

The dorsal surface of the roof of the internasal septum is surmounted by a pair of dermal ossifications (Figs. 3, 22) which lie on each side of the median line of the head. Near the anterior end of the cranium they fuse to form a single median plate. The anterior ventral surface of this plate is fused to the underlying perichondrial ossification by osseous trabeculae; posteriorly there is a layer of connective tissue between these two ossifications. The paired posterior pieces of the dermal ossification interdigitate with the anterior ends of the paired frontal ossifications above the posterior end of the internasal septum. The dermal element is the beginning of the dermo-supraethmoid part of the adult bone, and the perichondrial, the auto-supraethmoid part.

In the 60 mm. stage these ossifications have covered the ethmoid cornua and extend laterally above the anterior end of the nasal fossa. There is also a perichondrial and a dermal ossification on the ventral surface of the ethmoid cartilage, which, though not apparent in the 32 mm. stage, are well developed, and fused with each other in the 60 mm. stage. Both dorsal and ventral dermal elements extend anteriorly beyond the cartilaginous cornua and fuse with each other, forming a sharp anterior cranial edge, notched medially. A small pocket is left in the wall of the nasal fossa between the lateral edges of these ossifications which persists in the adult. The rudiment of the premaxillary bone is fused to the ventral surface of the ventral dermal ossification.

A thin flat plate of osseous tissue, derived from the ossification of a membrane, lies along the lateral margin of the dorsal part of the ectethmoid process (Figs. 3, 4). It projects laterally above the anterior end of the orbit and the orbital foramen, and is the dermal portion of the ectethmoid ossification. The rest of the ectethmoid process has hardly begun to show signs of ossification and yet this dermal part extends from the anterior end of the orbit to the palatal articular surface (Fig. 3). Perichondrial ossification has taken place on the ectethmoid process around this articular surface (Fig. 4), but the surface itself remains unossified. Thus the early ectethmoid bone has both auto and dermal parts.

Two lateral line bones, the nasal and the lacrimal (Fig. 3, 22), form a part of the roof of the nasal fossa on each side. The nasal (*na*) is a long straight ossified tube extending parallel to the supraethmoid and separated from it by a narrow space. It contains the anterior end and opening of the supraorbital latero-sensory canal. The process of the formation of such a bone as this has been described by Platt (1893) and Klaatsch (1895), so that it is unnecessary to repeat it here.

The lacrimal lies near the ventro-lateral margin of the roof of the nasal fossa and contains the anterior end of the suborbital latero-sensory canal. Its triangular outline is due to the division of the canal into two tubes for communication with the exterior. Ventro-posteriorly it articulates with the anterior ossicle of the infraorbital series (Fig. 3) and anteriorly it is fastened by connective tissue to the dorsal surface of the palatine ossification (*pal*). Be-

tween the posterior portions of this bone and the more medial nasal, the roof of the nasal fossa is formed by the cartilage which supports the nasal barbel (Fig. 22). This has no connexion with the chondrocranial cartilage and has been named, the 'Nasenflügelknorpel,' in the Characinidae by Sagemehl (1885), who regarded it as the phylogenetic remnant of the nasal-flap cartilage of the Selachians.

The rudiment of the vomer (Figs. 4, 22) appears as an unpaired dermal ossification ventral to the perichondrial ossification on the inferior surface of the ethmoid cartilage. These two ossifications are distinct and have no connexion as did the two types of ossification on the superior surface. There are no teeth on the early vomer, which interdigitates posteriorly with the anterior projections of the parasphenoid ossification by two pointed processes. This interdigitation takes place below the posterior margin of the ethmoid cartilage.

The ethmoidal region of the developing Ganoids is, as far as is known, entirely cartilage at a stage comparable to the 32 mm. stage of *Amiurus*. The only place where perichondrial ossification has appeared is around the ectethmoid process. The supraethmoid ossification is a distinctly dermal bone, comparable to the dermo-supraethmoid of *Amiurus*, but has a transverse lateral-sensory canal ossification on its dorsal surface connecting the supra-orbital canals of the two sides. There is always a space, usually filled with connective tissue, between this ossification in the Ganoids and the underlying cartilage. The nasals of *Amia* are very much larger and flatter than the corresponding bone in *Amiurus* and lie on the ethmoid cartilage. These bones are developed in connexion with the latero-sensory canal system and enclose the anterior ends of the supraorbital canals. The large nasals limit the supraethmoid, so that it remains as a small triangular ossification at the anterior tip of the cranium. The massive internasal septum of the adult *Amia* is comparable to the same element of the 32 mm. *Amiurus*. The prefrontal ossification (my ectethmoid) of *Amia*, is limited, even in the adult, to a small area around the dorso-lateral margin of the ectethmoid process; whether or not it develops perichondrially is not known. The vomer in *Amia* is paired and toothed on its ventral surface, and is limited, as is the vomer of *Amiurus*, to the medial part of the ventral surface of the cranium. As in *Amiurus*, the palatine articular surface remains as cartilage.

The ethmoidal region of the 32 mm. *Amiurus*, in its cartilaginous parts is somewhat like that of a 25 mm. *Salmo*, as described by Gaupp. There is the same massive cartilaginous internasal septum flanked by the nasal fossae, but the anterior end of the ethmoid cartilage is rounded in *Salmo* and no ethmoid cornua are present. The postero-dorsal extent of the ectethmoid process is approximately the same in both cases, relative to the anterior end of the orbit, but the foramen orbito-nasale is much higher in the cranial wall and farther

posterior in *Amiurus* than in *Salmo*. The large tectum cranii is not present in *Amiurus*.

The oblique eye muscles of *Amiurus* have no relation to the ventral surface of the ethmoid cartilage as in *Salmo*. Because of the development of an interorbital septum, the trabecular wall of the orbit has disappeared and the olfactory nerve crosses the orbit and penetrates the ectethmoid process to reach the olfactory organ. Gaupp (1906) probably selected the salmon as his type of teleost development because of the ease of obtaining material, although it is more highly specialized in many parts in which the Siluroids are almost schematic. The ethmoid region is an example of this, and I think the general development of the ethmoidal region in the Siluroids is more primitive than is the same region of *Salmo*.

Gaupp says (06; p. 676): "Die Ersatzknochen occupieren das Chondrocranium bei den Teleostiern in sehr verschiedenem Umfange; meist bleibt ein sehr beträchtlicher Teil von ihm in knorpeligen Zustände erhalten. Die Zahl der einzelnen Ersatzknochen ist dabei ziemlich gross, aber ihre Ausdehnung ist beschränkt. Und zwar können, wie bei den Ganoiden, nicht nur zwischen den einzelnen Stücken grösseren Knorpelzonen bestehen bleiben, sondern bei manchen Formen dringen die Knochen auch nur wenig in die Tiefe des Knorpels ein, so dass die Zerlegung des Knorpelschädels in knocherne Territorien sehr unvollständig sein kann (*Alepocephalus rostratus*, Gegenbaur). Die Ethmoidalgegend bleibt häufig in grössten Ausdehnung knorpelig."

The ectethmoids of *Salmo* (pleurethmoidale, Gaupp) are formed by perichondrial ossifications around the ectethmoid process and a ligamentous connexion with the palatine ossifies with them. A large laterally lying dermal ossification such as is found in *Amiurus* is not mentioned.

When ossification first appears in *Gasterosteus* (Swinerton, 1902), the ethmoid region of the cranium is greatly elongated in a manner somewhat comparable to the condition in *Amiurus*. The preethmoid cornua are very elongate and have a separate ossification not found in *Amiurus*, but which Swinerton compares to the septo-maxillary bones of *Amia*. Concerning the mesethmoid (supraethmoid, author), he says: "In the anterior portions of the skull the expanded plate-like portions of the parethmoid cornua have given rise to the parethmoid bones (figs. 4, 9, *e p b*), whilst a center of ossification, the mesethmoid, has appeared on the dorsal surface of the corresponding cartilage. The edges of the latter ossification extend freely into the surrounding tissue, and give the impression of a membrane bone whose central portion has united with the cartilage leaving the edges quite free."

Evidently Swinerton did not study the histological relations of this dermal plate to the underlying cartilage or he would probably have observed a condition similar to that in *Amiurus* and what Allis (1910) found in the young *Scorpaena*. The latter author says: "The mesethmoid of *Scorpaena*, although undoubtedly a so-called primary bone, consists of two distinctly different portions.

One of these portions is a thin dense layer of superficial bone. The other portion is a deeper one, of quite different appearance, which underlies the central portion only of the superficial portion, and there replaces portions of the cartilage of the skull. . . . The superficial portion of the bone is represented by a thin plate that lies closely upon the cartilage of the skull, without intervening membrane, and must primarily be wholly of perichondrial origin; But this perichondrial plate receives at certain places, accretions or additions to its outer surface, and these accretions, although they present in sections exactly the same appearance as the perichondrial plate, seem to be of purely perichondrial origin. This is particularly noticeable, in my specimens, along the lines of articulation of the mesethmoid with the frontals, and in the mesethmoid process."

This is identical with the condition in *Amiurus*. The ectethmoidal relations are also practically identical in the two forms. They are both of perichondrial origin with a dermal ossification in the form of a large wing of bone added to them. The other relations of the ethmoidal bones are best discussed in connexion with the adult cranium.

*The orbital region.* The orbital wall of the cranium at this stage is formed by the persisting and enlarged alisphenoid cartilage (Figs. 3, 4), together with the ossifications above and below it. It extends from the posterior face of the ectethmoid process as far posteriorly as the anterior end of the otic capsule. The cartilage in this region has grown considerably since the 10 mm. stage, but it has approximately the same topographical relation to the otic capsule and to the optic, trigeminal and facial nerves. The dorsal margins for the foramina of these nerves is as yet formed by the unossified cartilage.

Below the ectethmoid process the cartilage of each wall fuses with the anterior end of the trabecula cranii of that side and, as in the younger stage, forms the posterior margin of the orbital foramen, separating it from the optic foramen (Fig. 4). The posterior margin of the latter foramen has developed from the ossification of the membrane which, in the 10 mm. larva, extended from the alisphenoid cartilage to the trabecula. This ossification (Fig. 32) is not a continuum, but is divided into a dorsal and ventral part. The dorsal part is continuous with the perichondrium of the alisphenoid cartilage as was the membrane of the young animal, but the relations of the ventral part are not so simple and will be taken up in the discussion of the trabecular region. This ossified wall is continued as far posteriorly as the trigeminal nerve (Fig. 4) and forms the anterior margin of its foramen; the dorsal margin has been described above as formed by the alisphenoid cartilage proper (*alis. c.*). The posterior margin of this foramen, through which the main branches of the facial nerve also issue, is formed by a perichondrial ossification (Fig. 4) between the ventral wall of the otic capsule and the posterior end of the trabeculae.

The foramen for the passage of the ophthalmicus superficialis trigemini (Fig. 4, *oph. V.*), which earlier was entirely in cartilage, has now ossified on its ventral external side, so that the nerve is enclosed in an osseous canal posterior to and above the optic foramen. The ophthalmicus superficialis facialis (Fig. 4) issues through a foramen in the cartilage just above the opening of the osseous canal of the ophthalmicus superficialis trigemini and innervates the lateral line canal organs of the anterior part of the supraorbital canal which lie in the frontal and nasal bones (Fig. 11).

The roof of the cranium posterior to the internasal septum is formed by the frontal ossifications (Fig. 3) and the very thin cartilaginous epiphysial bar. The latter is now relatively much farther posterior to the ethmoid region than it was previously and lies in about the same transverse plane as the optic foramina. Dorsally it is covered by the broad frontals, which are separated from each other in the mid-dorsal line by a very narrow fontanelle except in the region immediately above the epiphysial bar where they interdigitate. These frontal ossifications are the largest in the roof of the cranium at this stage; they project laterally above the orbit in continuation with the dermo-oectethmoid (Fig. 4). The ventral surface of the frontal sits on the dorsal surface of the alisphenoid and tegmen cranii cartilages (Figs. 32, 39) and extends down the outside face of the former without being at all intimately connected with the perichondrium of the cartilage. Behind the eye each frontal is grooved for the reception of the suborbital lateral line canal and articulates with the posterior ossicle of the infraorbital series (Fig. 3). The suborbital canal enters the frontal at this point and unites with the posterior end of the supraorbital canal to form a canal which extends posteriorly on to the dorsal surface of the (Fig. 11) sphenotic; this condition persists in the adult. The ossification surrounding the supraorbital canal (Fig. 32.) is indistinguishably fused with the membranous frontal ossification. This canal runs anteriorly within the frontal to a point just posterior to the union of the supraethmoid and frontal, and from here passes into the connective tissue surrounding the posterior end of the nasal bone and thence into the latter (Fig. 11.). From the junction of the supraorbital and suborbital canals, a tubule, enclosed in an osseous canal, runs obliquely posterior toward the middle line of the frontal and opens through a small pore on its dorsal surface (Fig. 3, *t. p.*). Another dermal tubule leaves the frontal through a pore in its dorsal surface just posterior to the entrance of the supraorbital canal into the frontal from the nasal (Fig. 3, *t. p.*)

The infraorbitalia (Fig. 3) are a series of slender, cylindrical, pipe-like bones, beneath and behind the eye, including within them the suborbital lateral line canal. They are six in number, each separated from its successor by the passage of a tubule from the enclosed canal to the external surface of the head, a so-called dermal tubule (Fig. 11.) The most anterior bone of this series connects with the ventro-lateral margin of the lacrimal bone into which the suborbital lateral line canal passes. These bones are typical of the teleosts.

The anterior part of the alisphenoid cartilage, as we have noted, is unossified at this stage (Figs. 3, 4,) and is probably converted into the orbitosphenoid bone of the adult which appears in this region (Figs. 16, 20). The perichondrial ossification between the optic and trigeminal foramina (Fig. 4) is the beginning of part of the alisphenoid bone of the adult (Fig. 20).

In the younger stage the internal carotid artery enters the cranium internal to the trabecula (Fig. 2 ca), but now it has a different relation. This blood vessel enters a rete mirabile, lateral and posterior to the optic foramen, and a branch to the internal part of the cranium enters through the posterior part of the optic foramen. The external carotid enters the cranium as before, between the branches of the trigeminal nerve.

The ramus oticus of the facial nerve (Fig. 3 *rot. VII*) issues through the dorsal posterior margin of the alisphenoid cartilage just anterior to the otic capsule, and proceeds posteriorly within the lateral line canal ossification on the sphenotic bone to innervate a canal sense organ.

Speaking in a general way of the orbitosphenoid development throughout the whole vertebrate series, Parker and Bettany say that it is the result of the ossification of the anterior part of the lateral cranial wall, and may be either anterior to or penetrated by the optic nerve. It also arises from paired centers, although in the adult it may be unpaired. It is described by these authors in *Salmo* as an 'ectosteal' (comparable to my term perichondrial) lamina in the anterior part of each side wall of the cranium. Concerning the development of the same bone in *Salmo*, Gaupp (1906) says that it is developed in the dorso-anterior part of the interorbital septum and the ventral surface of the tegmen cranii of this region, and, further, the olfactory nerve issues through it before entering the orbit. Since an interorbital septum is absent from *Amiurus*, comparison with the *Salmonoid* condition is not very easy and clear to the casual observer. But if we can conceive of the cranium of *Amiurus* being compressed instead of depressed, then the anterior ends of the alisphenoid cartilages, where they unite with the ectethmoid process, would be pushed together, and the surface where they met would be comparable to the interorbital septum. At this stage of *Amiurus* there is no ossification on the dorsal part of the anterior end of the alisphenoid cartilage in the region of the anterior part of the optic foramen, although the perichondrium shows signs of the beginning of a perichondrial ossification, both on the outer and inner surfaces, which extends down to the trabecula. The first traces of the orbitosphenoid occurs in the *Salmon* at the 35 mm. stage.

The alisphenoid of the salmon is a later ossification than the orbitosphenoid, whereas in *Amiurus* it is quite well developed before any great development of the orbitosphenoid. Speaking of the alisphenoid in *Salmo*, Gaupp (1906) says: "Entsteht sehr spät (*Salmo fario* von 40 mm.) in Form von zwei perichondrialen Knochenlamellen, einer inneren und einer äusseren, auf der knorpeligen Schädelseitenwand vor der Ohrkapsul. Im Anschluss an den

perichondrale entstanden Abschnitt ossifiziert auch ein Teil der häutig gebliebenen Bettenwand der Orbitotemporal region. Das Alisphenoid schliesst in selbständige Foramina den N. Trochlearis und den ersten Ast des Trigeminus ein und begrenzt von oben her das Opticum."

The posterior alisphenoid ossification between the optic and trigeminal nerves of *Amiurus* has most of these characters given by Gaupp for the alisphenoid of *Salmo*, who says little about the nature of the 'hautig' wall and its relation to the trabecula. As I interpret it, this wall is developed at a very early age from the perichondrium of the alisphenoid cartilage, since they are intimately connected in the 10 mm. stage. The relations of the ventral part of this region will be taken up later in the discussion of the trabecular region. In *Salmo*, the ophthalmicus superficialis trigemini has a different course through the alisphenoid cartilage and is closer to the otic capsule than it is in *Amiurus*. Gaupp does not discuss the relations of the ophthalmicus superficialis facialis of *Salmo*.

Both alisphenoid and orbitosphenoid ossifications occur very late in the development of the ganoids in approximately the same place in regard to the passage of nerves as in the teleosts. In the Amphibia the orbitosphenoid (sphenethmoid; Parker, 1872) is developed on the anterior end of the alisphenoid-trabecular cartilage and the posterior margin of the ethmoid cartilage, in approximately the same position that it has in *Amiurus*. The alisphenoid ossification does not form.

As mentioned above, Gaupp (1902) claims that the alisphenoid of the mammalian cranium is developed from a newly added cartilaginous part, the 'ala temporalis,' but I have adopted a different view, and believe that the cartilage is the same in both Mammals and Ichthyopsida, because of its relation to the trigeminal nerve. Gaupp himself admits that nerves are good landmarks in the establishment of homologies and yet denies this homology.

The frontal bones first appear developmentally in the Acipenseridae (Parker; 1882) and the lower Siluridae (Hertwig; 1876), as dermal plates, slightly separated from the corium and having their origin in this layer. They never form a pair of distinct frontalia as in *Polypterus*, *Amia* and *Lepidosteus*, but remain as groups of plates. They do not touch the cartilage of the tegmen cranii, but are separated from it by connective tissue. Walther (1882) found that the frontalia in *Esox* develop in the same way, but were nearer the cartilage and had less relation to the corium. Williamson (1851), Heincke (1867), Hertwig (1876), came to the conclusion that the frontals of the teleosts and ganoids were descended from dermal scales, a view now universally accepted for all osseous vertebrates.

Vrolik (1873), in his discussion of the development of the frontals in the teleosts, remarked that they were formed for the protection of the lateral line canal which, in the adult of most teleosts, runs along the dorsal surface of the bone. Walther (1882) in his work on *Esox* denies that such a condition exists,

because the centres of the frontals appear before there is any trace of the lateral osseous canals, and that, in some forms, the osseous canals are entirely separate from the frontals throughout life, but in the majority of forms they fuse with the underlying independent frontal. The frontals of *Amiurus* bear out this latter statement, since the rudiments appear as paired membranous sheets roofing the large fontanelles. The lateral line canal ossification arises independently of this membrane and only secondarily becomes connected with it. This independence of ossifications shows especially well in the relation of the ossification surrounding that canal extending from the junction of the suborbital and supraorbital canals toward the middle line of the head; here the canal ossification is very distinct from the underlying frontal. At this stage in *Amiurus* the frontals have practically the same relations to the surrounding bones that they have in the adult cranium.

The infraorbital chain of bones, whenever developed, is related to the suborbital lateral line canal, and in most cases the component bones of the chain are larger and flatter than in *Amiurus*, a condition usually correlated with the development of the eye.

The anterior ends of the trabeculae are as yet continuous with the posterior end of the ethmoid plate, although the fenestra hypophyseos is more posterior than it was in the younger stage (Fig. 3). They are no longer continuous bars from the ethmoid plate to the parachordal plate, but half way between these regions a part of each has been resorbed and parasphenoid and suprasphenoid ossifications have replaced it by growth dorsally into this region, forming the posterior margin of the optic foramen and part of the margin of the trigemino-facial foramen (Fig. 4).

The trabeculae of the two sides are connected across the anterior end of the fenestra hypophyseos by a perichondrial ossification, separated by a wide space from the more ventrally situated parasphenoid ossification (Fig. 4). This ossification lies in the floor of the cranium between the optic foramina. Anterior to these foramina the trabeculae are united to the anterior ends of the alisphenoid cartilages to form the cranial wall between the orbital and optic foramina as in the 10 mm. stage. Toward the posterior end of the optic foramina, the perichondrial connexion between the trabeculae disappears, and osseous trabeculae, the centre of the suprasphenoid bone, extend dorsally from the parasphenoid ossification, which now forms the medial cavum floor (Fig. 32). Farther posteriorly, the suprasphenoid ossification extends above the trabeculae and meets the lateral margins of the parasphenoid external to them, thus encasing the cartilage in an osseous sheath, unconnected with the perichondrium. In this immediate region, just back of the preceding part, between the optic and trigeminal nerves, the cartilage of the trabecula disappears (Fig. 3), and the suprasphenoid ossification is connected with the parasphenoid by osseous trabecula across the space formerly occupied by the cartilage. The ossification extends dorsally in the cranial wall and, with a ventral ossified spur

from the alisphenoid cartilage (Fig. 4), forms the wall between the optic and trigeminal nerves.

Ventral to the trigeminal nerve, the cartilage reappears within the ossification, but unconnected with it as before. This cartilage becomes larger posteriorly, until, posterior to the passage of the facialis nerve, ossification has again become limited to the median ventral surface and has only a couple of splints protruding into the cavum cranii (Fig. 3) through the anterior fenestra basicranii.

The question now arises as to the proper designation for this part of the basal fenestra, which lies behind the hypophysis, in the salmon (Parker, 1872; Gaupp, 1906) it is termed the fenestra basicranii anterius, in contradistinction to a more posterior parachordal fenestra. The cartilaginous plates on either side of the cranial floor in this region of *Amiurus* have grown anteriorly in concert with the otic capsules, since their lateral ends are confluent with the perichondrial ossification of the ventral side of the otic capsules (Fig. 4). The small medial space between them is a fenestra between the anterior parachordals and is therefore comparable to the corresponding fenestra in *Salmo* and may be so designated. It is evident therefore, that the connexion between trabeculae and parachordals has disappeared by resorption of cartilage. The dorsal ossification on the parasphenoid, the suprasphenoid, has taken its place.

In *Gasterosteus* (Swinnerton, 1902) the trabecular cartilage has disappeared in this region as in *Amiurus*, but the floor of the cranium is formed by the parasphenoid, except in the region of the eye-muscle canal; here there is an ossification corresponding to the suprasphenoid of *Amiurus*. Unfortunately the details of the development of this region is not known. The modifications of the basal part of the cranium, in forms having an interorbital septum, where the parts are all compressed, are not easily homologized with the depressed condition of the same region in *Amiurus*, and in making comparisons, this fact always has to be borne in mind. Also the absence of an eye-muscle canal in *Amiurus* makes for differences in the development of the basal parts between the orbits.

In *Salmo* there is an elongate trabecula communis (Parker, 1873; Winslow, 1897; Gaupp, 1906) which is concave below and bears the membranous interorbital septum on its crested dorsal surface. I have found no mention of a perichondrial ossification around this trabecula communis, such as is found at the anterior ends of the trabeculae in *Amiurus* between the orbits, and which is the anlage of the orbitosphenoid of the adult. The parasphenoid has the typical relation to the floor of the cranium that it usually has in the Ichthyopsida.

McMurrich (1884b) has described a basisphenoid in this region of the adult *Amiurus*, as an "indistinct ossification completely fused with the parasphenoid." I have remarked above that there is an ossification on the dorsal surface of the parasphenoid between the trabeculae and have it named the supra-

sphenoid. In the piscine nomenclature commonly used at the present time, this ossification is regarded as the basisphenoid, although it has been known for a long time that it is not the homologue of the basisphenoid center of ossification of man, from which the terminology is derived. In all fishes where it appears as a distinct bone, it lies anterior to the hypophysis and is developed from connective tissue membrane. Cuvier called it the 'sphenoide anterieur,' but Hallmann (1837) pointed out that Cuvier's diagnosis of this bone as the homologue of the presphenoid region of man was incorrect. Concerning this bone, Hallmann says: "Ein vorderer Keilbeinkörper wäre wie bei die Säugthieren und wie als der Name sagt, vor dem hintern zu suchen. Aber mit Cuvier (der die Knochen Fig. 24 g und Fig. 25 u. 26 beide vordern Keilbeinkörper nennt) einen auf den vordern Theil des Keilbeins oder auf die Mitte desselben sich herabsenkenden Knochen Keilbeinkörper nennen, heisse aller Analogie."

Reasoning upon this basis and continuing to regard the parasphenoid as the homologue of the basisphenoid of the mammalian cranium, he named the bone in question, the 'sphenoide superior' and maintained that it was found only in fishes and that it had varying developments in these.

Huxley (1864) studied the development of the parasphenoid in *Esox* and concluded that it was a dermal derivative and hence not the homologue of the basisphenoid ossification center of man, a purely cartilage development posterior to and below the hypophysis. He named Hallmann's 'sphenoide superior,' the basisphenoid, but remarked that it was only comparable to the anterior part of the basisphenoid and that the rest of the element persisted as cartilage. His reasons for regarding this bone as the homologue of the basisphenoid are, that in the foetal human skull the basisphenoid contributes nothing toward the posterior boundary of the pituitary fossa, which is formed by the long cartilaginous synchondrosis which connects the rudimentary basisphenoid with the basioccipital. Thus he regarded the bone as a rudimentary basisphenoid. Owen, following St. Hilaire, called it the entosphenal, and regarded the parasphenoid as divided into a presphenoid and basisphenoid part, regardless of the work of Huxley. Allis (1897) regarded it as the homologue of the presphenoid bone of man and yet called it the basisphenoid.

The development of this bone is the keystone in making the homologies, and all who have studied its development have found that it develops from connective tissue membrane anterior to the hypophysis, and hence cannot be the homologue of the basisphenoid bone of man—a cartilage bone developed from the basis cranii. The cartilage which is enclosed within the parasphenoid and this ossification in *Amiurus* may be the homologue of the basisphenoid which never ossifies. This is an ossification peculiar to fishes and, together with the parasphenoid, it becomes gradually replaced in the higher vertebrates by the ossification of the basis cranii. Since it is neither the homologue of the basisphenoid nor of the presphenoid, it must be regarded as a distinct bone and

hence the name proposed a priori by Hallmann (1837), the 'suprasphenoid,' may be applied to it, although it is to be understood that his criteria for distinguishing it are not used as the basis of the terminology, but rather its independence as a connective tissue ossification above the parasphenoid and between the ventral ends of the alisphenoids.

Schleip (1903) says that in *Salmo* the bone arises from a direct ossification of the membranous wall at the anterior end of the eye-muscle canal, and that it is indirectly connected to the parasphenoid and the alisphenoids by membrane which later ossifies. He recognizes it as part of the elements of the primordial cranium which has no cartilage stage and says, p. 378;

"Das Bindegewebe, aus dessen Ossifikation sie hervorgehen, geht in Teile des Knorpelschädels über, verschliesst also lucken, die der Knorpelschädel aufweist, und ist daher wohl nicht zu weit gegangen, wenn man es als Anlage des Primordiacranium gehörig auffast, als ein Teil desselben, der nicht zur Verknorpelung kommt."

Even assuming this view to be true, the morphological relations of the bone must be considered before it can be called the basi- or presphenoid.

The parasphenoid of *Amiurus* in its development is like the large parasphenoid of the *Urodeles* which develops between the trabeculae and forms the floor of the cranium in this group. Its lateral edges form the ventral margin of the lateral wall of the orbital region as in *Amiurus*. It is related to the orbitosphenoid in the anterior region, just as the parasphenoid of *Amiurus* is related to the ossification around the anterior ends of the trabeculae. In the 10 mm. stage of *Amiurus*, the place occupied by the parasphenoid of the 32 mm. stage is closed by a membrane which is separated from the trabeculae and already shows signs of extending above and below them. In *Amia*, the median floor of the cranium is continuous cartilage, a condition arising from growth medially of the trabeculae, and the whole hypophysial fenestra is closed, except for a small part just below the hypophysis, which is closed by the parasphenoid. The parasphenoid here has the same superficial extent on the ventral surface that it has in *Amiurus*, but its growth dorsally is restricted by the cartilaginous cranial base. The orbitosphenoids of *Amia*, one on either side of the cranium, are situated around the anterior margin of the optic foramina, but do not have the same ventral extent as the ossification around the anterior ends of the trabeculae of *Amiurus*.

*The parachordals.* In the 10 mm. larva of *Amiurus*, the parachordal plates posterior to the hypophysis, were rather widely separated from each other (Fig. 2). Laterally they were continuous with the cartilage of the anterior end of the otic capsules, this cartilaginous connexion forming the posterior margin of the trigemino-facial foramen, (Fig. 2). In the 32 mm. larva this is replaced by a thin lamella of perichondrial bone (Fig. 4). It appears as if this condition arose from the earlier one by a growth of the otic capsule and the

parachordal away from each other, without a corresponding growth of the immediate connecting region.

Posterior to the hypophysis, the parachordals gradually approach each other and the fenestra between them narrows to a mere slit as compared with the wide fenestra in this region of the younger cranium. The parasphenoid ossification forms the floor of this fenestra and a couple of processes from its dorsal surface project into the *cavum cranii* (Fig. 4, *Ps.*). With fusion of the parachordals with each other farther back, the parasphenoid is excluded from the floor of the *cavum cranii* and lies ventral to the cartilage thus formed (Fig. 27). In the layer of osteoblasts between the periosteum of the parasphenoid and the cartilage the anterior projection of the perichondrial ossification on the ventral surface of the posterior part of the basal plate, appears as a couple of spicules.

At the line where the parachordals (Fig. 4) fuse with each other, they also form a cartilaginous continuum with the otic capsules, the perichondrium of which is ossified. Laterally and above the parachordal-otic capsule fusion, the cartilage of the capsular wall, which was thick in the younger stage, is reduced to an osseous plate continuous with the perichondrium of the cartilage above and below it (Fig. 4). The edges of this thin region are abrupt and the macula utriculi abut against the wall, giving evidence that the thinness of the wall was caused by the lateral growth of the utriculus.

There is a small recess in the floor of the cranium on either side in the region where otic capsule and parachordal fuse. Each recess is covered dorsally with a thin lamella of bone and osseous trabeculae (Fig. 27) extend across its lumen. Proceeding posteriorly, these recesses converge and the anterior ends of the sacculi appear within them (Fig. 27). These recesses were not present in the younger stage, but have been caused by the anterior growth of the sacculi beyond the canal sinus imparis, and subsequent growth of the cartilage of the floor around them. The osseous roof above these recesses is apparently formed by the ossification of perichondrial strands from this cartilage (Fig. 27). These recesses contain the anterior ends of the sacculi ('processes of Comparetti,' Wright, 1884) and are said to lie within the prootic bones of the adult. For a short distance posteriorly the 'processes of Comparetti' are separated from each other by a median crest of cartilage (Fig. 28), the dorsal surface of which is grooved and filled with osseous trabeculae of perichondrial origin. The sacculi grow larger as they approach the canal sinus imparis (Fig. 28), the median cartilage diminishes in amount and the two recesses come closer together. The osseous roof of each recessus disappears in this region where the ramus saccularis of the auditory nerve descends to innervate the macula sacculi (Fig. 28). Just posterior to this innervation the sacculi of the two sides are connected with each other by the canal sinus imparis.

In the other teleosts whose developmental history has been followed, the ossifications which arise in this region around the anterior parachordals and

the ventral ends of the otic capsules, have been described as the centres of the prootics. Schleip (1903) says: "Die ersten Spuren von Verknöcherung treten bei einem Lachs von 24 mm. Länge auf: das Prooticum besteht hier aus einer inneren und einer äusseren, den Knorpel in der Umgebung des Facialisloches umfassenden perichondrialen Knochenlamelle; ein Zusammenhang beider an der Rändern des Foramen ist aber nirgends vorhanden, vielmehr entbehrt die Wand des Facialiskanals selbst den Knochenüberzug noch vollständig (Siehe Fig. 5). Die genannten Lamellen sind wie überhaupt alle perichondralen Verknöcherungen auf diesem Entwicklungsstadium homogen, scharf vom Knorpel wie vom Bindegewebe abgesetzt und haben kein anderes Reliefe, als es durch die Anlagerung an die Knorpeloberfläche bedingt ist; wenige schmal, spindelige Zellen bilden das Periost."

In the salmon, however, the eye-muscle canal is formed by the inward growth of the rectus eye muscles between the parachordalia and the cavum cranii, a membranous bridge roofing the canal so formed, and supporting the brain. The homology between *Amiurus* and *Salmo* in this region is easily seen, despite the specialization in the latter. In both, the parachordalia are continuous with the otic capsules posterior to the hypophysis and there is the narrow fenestra basicranii anterior between them, the floor of which is formed by the parasphenoid ossification. There are the same inner and outer perichondrial lamellae as described by Schleip (1903), but in *Amiurus* at this stage these lamellae have united. The 'processes of Comparetti' do not occur in *Salmo*, but are limited to the *Ostariophysi*. The relations of these processes to the cartilage of the floor of the cavum and to the cavum itself are very similar to the eye muscle relations and have arisen by an invasion of the cranial floor. The thin osseous wall of the otic capsule, described above, is formed in the same way as in *Salmo* (Schleip), by the disappearance of the inner lamella and resorption of the underlying cartilage, so that the wall is formed by the outer lamella alone.

In *Amiurus*, the cartilaginous wall (Fig. 4) lateral to the utriculo-saccular connexion is very thick and is continuous dorsally with the septum semicircularis laterale. That part of the parachordal which contains the sacculus forms an angle of about 120 degrees with the otic capsule proper. The glossopharyngeal nerve issues from the cranium dorso-lateral to the sacculus and between it and the utriculus (Fig. 4). The anterior margin of its foramen is formed entirely of cartilage, (Fig. 4). Posterior to the passage of this nerve the sacculi are again enclosed in recesses as were their anterior ends. The ossifications which form the roof extends transversely from between the two jugular foramina (Fig. 26) and meet by suture medially below the brain. From the ventral surface of each of these ossifications, an ossified bar extends obliquely toward the midventral surface of the basal plate. This basal plate is triangular in cross-section and forms a cartilaginous crest between the recessus sacculorum. It is surmounted by a perichondrial ossification which has two diverging proc-

esses connected by sutures to the descending processes of the roof plates of the recessus sacculorum. Thus there are formed three chambers; the two lateral contain the sacculi and the lagenae, while the medial unpaired chamber contains the sinus impar of the Weberian apparatus, and is called the *cavum sinus imparis*. The floor of each recessus sacculi is formed by a thin osseous lamella, as the cartilage which was originally in this region has been resorbed and the perichondrial ossification alone remains. The ventral surface of the median basal plate is covered by a thick perichondrial ossification which extends laterally beneath the recessus sacculorum and with which the parasphenoid ossification interdigitates. In cross-section, the notochord appears as a very small circular area within the median basal plate, the tip lying just beneath the region of the canal sinus imparis. In the younger stage it extended anterior to this connexion and in this immediate region was very large in comparison with the amount of the surrounding cartilage. The plate at that stage (10 mm.) was divided into halves (Fig. 8), but now forms a continuum above and below the notochordal tip (Fig. 27).

The amount of cartilage around the notochord gradually diminishes toward the posterior end of the cranium, while the diameter of the notochord increases (Fig. 26). The whole floor of this region has become deeper and narrower than it is anteriorly and the ossification in the floor of the recessus sacculorum has replaced the cartilage entirely. The former cartilage between the glosso-pharyngeal and vagus nerves, has been resorbed and the lamella formed by the ossification of its outer perichondrium alone is left, separating the two nerves (Fig. 4). The vagus nerve issues posterior to this lamella through a very elongate foramen (*x*) between the otic capsule and the dorso-lateral edge of the recessus sacculi of that side. Posterior to this foramen the perichondrial ossification at the ventral end of the occipital arch is continuous with that on the roof and side walls of the recessus sacculi. This lamella is, however, only an anterior projection of the perichondrial lamella around the anterior surface of that part of the occipital arch which joins the cartilage of the roof of the recessus more posteriorly (Fig. 23). This cartilage is not very great in extent (Fig. 23) and osseous trabeculae again appear between the saccular recesses and the posterior ventral end of the occipital arch. The hypoglossus nerve, which in the younger stage issued from the cranium through a rather large space, is now enclosed within this osseous mass (*ex*).

Solid cartilaginous masses on each side of the notochord mark the posterior ends of the recessus sacculorum, just posterior to the passage of the hypoglossus (*pch*). These cartilaginous masses extend farther posterior than in the younger stage and rise higher on the sides of the notochord (compare Figs. 17, 23) so that there is a groove between them filled with osseous tissue (Fig. 37). The whole notochord is surrounded with osseous tissue and there is an hypochordal cartilage present on its ventral medial surface. This piece of cartilage was not developed in the 10 mm. stage. Anterior to the hypochordal cartilage

the centre of the basioccipital on the ventral surface of the parachordal plate is thick and spongy, and continuous with the ossification surrounding the notochord. The transcapular processes of the shoulder girdle are fused with the perichondrial ossifications on the lateral surface of the posterior end of the parachordals.

McMurrich (1884b), from a study of young *Amiurus*, 20 to 38 mm. long, concluded that there never was a preformation of cartilage in the floor of the sacculi in this region. Cartilage occurred here in the 38 mm. stage, but he stated that it was due to the growth anteriorly of the cartilage at the very posterior end of the cranium. I have observed cartilage in this region in the 10 mm. stage, and the ossification at the 32 mm. stage which forms the floor of the recessus sacculorum is the result of the perichondrial ossification of the original cartilage, the cartilage itself having been resorbed.

The anterior processes of the scaphia, which, in the 10 mm. larva, lie immediately dorso-lateral to the notochord (Fig. 12), are now separated from it by paired cartilaginous masses (Fig. 37), the posterior continuation of the posterior parachordalia. These are covered ventrally with the perichondrial anlage of the basioccipital and latero-dorsally with that of the exoccipital. Posterior to this region the notochord is relatively much larger than it is intercranially. The endorhachis which supports the spinal cord and divides the sinus impar into the atria sinus imparis is more compressed than in the younger stage. It widens posteriorly in the region where the anterior processes of the scaphia fuse with the scaphia proper (Fig. 29), which are as yet of cartilage and articulate by rounded surfaces with the notochord. The claustra are better defined than in the younger stage; they lie between the scaphia and the anterior end of the third neural arch, forming the wall of the vertebral canal in this region. The second post-vagal nerve issues posterior to the scaphium (Fig. 35). The most striking morphological feature of this region is the posterior growth of the parachordalia and the subsequent separation of the anterior processes of the scaphia from the notochord (Fig. 37). The enclosure of the hypoglossus nerve within the cranium by ossification (Fig. 23) is comparable with the history of the same nerve in *Gasterosteus* (Swinerton, 1902) and the first two post-vagal nerves of *Salmo* (Harrison 1895; Willcox, 1899).

Schleip (1903) has described the formation of the ossifications around the parachordal cartilages and the ventral parts of the otic capsules in *Salmo*. He describes the basioccipital ossification as arising from paired inner and outer lamellae on the parachordals in the region of the fenestra basicranii posterius, into which the notochord projects. Anterior to the notochord the inner and outer lamellae meet across this fenestra, but in the region of the notochordal tip they are separated from each other by an osseous mass around the notochordal sheath, which he calls the 'ausfüllende Knochenmasse.' In *Amiurus* there is no fenestra around the anterior tip of the notochord and the ossification on

the inner perichondrium forms the walls of the cavum sinus imparis. The outer lamella is unpaired and is thicker in the middle line than on the sides, a contrast to the paired outer lamellae of *Salmo*. The paired rectus externus muscles are located in this region in *Salmo*. Further posterior in *Salmo*, the outer lamella has a spongy appearance, comparable to the appearance of the osseous lamella in the same region of *Amiurus* and which Schleip says arises from the ossification of fibrous connective tissue in that immediate region in connexion with the perichondrial ossification of the basal plate. From this comparison, I have concluded that the ossifications in this region are homologous and that they are the centres of the basioccipital of *Amiurus* as they are of *Salmo*.

The osseous lamella around the glossopharyngeal and vagus foramina and the ventral ends of the posterior semicircular canal and above the recessus sacculorum and cavum sinus imparis, have been described by Schleip and Gaupp as the centres of the exoccipitals. In *Amiurus*, the part above the sinus impar is preformed in membrane and only secondarily connects with the perichondrial ossification and hence cannot be exoccipital, though fused with it. The hypoglossus, in both *Salmo* and *Amiurus*, was not included within the cranium at an earlier stage, but is now enveloped in an osseous sheath between parachordal plate and the occipital arch.

*The otic capsules.* The cartilage enclosing each membranous labyrinth has grown considerably since the 10 mm. stage, but the relations of the septa semicircularia (Fig. 7) have remained the same. The detailed description of these, given for the younger stage, will also fit the 32 mm. stage and the adult, except for a change in size. The parts which merit description at this 32 mm. stage are the centres of the otic bones, which, in the teleosts, include prootic, sphenotic, pterotic, epiotic, and opisthotic. All except the last are present in *Amiurus*, according to McMurrich (1884b), and the problem is to locate and describe them in their earliest form.

These bones were first grouped as the otica by Huxley (1864), who called attention to the fact that they were developed around the otic capsule, which, as cartilage, had an independent origin and only secondarily became connected with the parachordalia and the occipital arch. Hence these bones formed a natural group in comparison to the other bones of the cranium. Vrolik (1873) objected to grouping of these bones as otics, and, because of the relation of the occipital bones to the labyrinth, maintained that these also could be included with the otica. As Van Wijhe (1882) later pointed out, this was due to a misunderstanding of the original statement of Huxley, because it is a well-known fact that the membranous labyrinth invades other bones than those which are developed around the capsule. Vrolik also claimed that the otic bones took no part in the formation of the cranial wall because he found the opisthotic to be variable bone, sometimes developed in the cartilage of the capsule wall,

again not related to the cartilage, and sometimes entirely wanting. We have no reason to believe that at some stage in the phylogenetic history of the vertebrates there was another ossification forming the wall of the cranium in place of the otic capsules of today. Could we prove that the otic capsule superseded an osseous or cartilaginous brain-case wall, only then could we say that the otic bones were not parts of the brain case.

The sphenotic is the most anterior dorsal of the otic bones and according to those who have studied its development in the teleosts, it appears as an ossification around the dorsal anterior end of the cartilage of the anterior semicircular canal recess, and of a part of the posterior end of the alisphenoid cartilage. In the 30 mm. *Salmo* (Schleip, 1903), the first sign of this ossification is an osseous lamella in the perichondrium of the postorbital process, which forms a ledge of bone projecting laterally above the hyomandibular articular surface and extending posteriorly along the roof of the anterior semicircular canal. The levator operculi muscle is attached to its outer surface. It spreads dorsally on the surface of the cartilage as far posteriorly as the pterotic ossification (which is developed on the roof of the lateral semicircular canal) and ventrally as far as the hyomandibula. At a later stage another perichondrial lamella is formed on the inner surface of the roof of the anterior semicircular canal. The formation of the adult bone takes place by the resorption of the cartilage between these two layers and by endochondrial ossification. Schleip makes no mention of the development of a lateral line canal ossification in connexion with the outer lamella. A fine nerve issues through the cartilage and bone in this region to innervate the sense organ of the lateral line canal contained in the pterotic ossification.

In the development of the sphenotic of *Gasterosteus* (Swinnerton; 1902), the inner lamella and the cartilage disappear, so that the wall is formed by the outer lamella alone.

In the 32 mm. larva of *Amiurus*, ossification is advanced, but I did not find any ossifications in this region of the 20 mm. larva. The ossification enclosing the supraorbital lateral line canal is intimately connected with the perichondrial ossification on the outer surface of the cartilage forming the roof of the recess for the anterior semicircular canal (Fig. 19). Just anterior to the cavum of the anterior semicircular canal, the ramus oticus of the facial nerve (the fine nerve of *Salmo*, Schleip, 1903) issues through the cartilage (Fig. 3) and divides into anterior and posterior branches; the posterior continues within the lateral osseous canal to innervate the next sense organ of the canal system. The perichondrial ossification and that of the lateral line canal cannot be distinguished from each other. Although there was no ossification in the 20 mm. stage in this region, the beginning of the lateral line ossification was represented by a heavy tract of osteoblasts surrounding the membranous canal. With subsequent ossification, the bone thus formed fused immediately with the underlying perichondrial ossification of the alisphenoid cartilage and the otic capsule. The

cavum of the anterior dorsal end of the skeletal anterior semicircular canal is filled with osseous trabeculae extending between the osseous lamellae in the perichondrium of its walls (Fig. 36). The outer lamella extends down on the side wall of the capsule as far as the hyomandibular articulation, but does not enter into the formation of the articular surface, which is as yet of cartilage. The abductor hyomandibularis muscle and the levator operculi are attached to the outer lamella, the former having the broader surface of attachment.

A part of the cartilage in the roof of the anterior semicircular canal recess has been resorbed together with the outer perichondrial lamella, so that the inner lamella forms the wall between the cavum of the recess and the lumen of the lateral line osseous canal (Fig. 19). This is just the reverse of the process that Schleip observed in *Salmo*, where the inner perichondrial lamella disappeared first. Toward the posterior end of the hyomandibular articular surface, the outer perichondrial lamella disappears and the lateral line ossification alone remains; it is separated from the underlying cartilage by fibrous connective tissue. This is the posterior end of the sphenotic, and when the perichondrial lamella appears again, it is on the dorsal surface of the lateral semicircular canal region of the otic capsule and is the centre of the pterotic ossification.

In the 60 mm. stage, cartilage resorption in the roof of the anterior semicircular canal recess has gone still farther, the outer and inner lamellae are indistinguishably fused with each other (Fig. 33), and endochondrial ossification has occurred, so that the place originally occupied by cartilage is now filled with osseous trabeculae. The cartilage near the posterior end of the roof of the recess still persists, and a thicker and spongier osseous mass projects laterally above the hyomandibular facet. Behind this, as in the 32 mm. stage, the lateral line ossification of the surface of the sphenotic passes on to the surface of the squamosal part of the succeeding ossification.

The ossification surrounding the lateral wall of the recess for the lateral semicircular canal, is the squamosal of most authors and the pterotic of Parker (1873). As part of the bone is preformed in cartilage and part of it of membranous origin a combination of these two names is preferable as it implies relationships which neither term used alone would signify. Hence I propose the name squamoso-pterotic for this mixed ossification.

Allis (1899) made a detailed study of the descriptions of this bone in different groups of fishes by the investigators before him. He says, in summarizing his review: "We thus see that the squamosal of fishes is composed of a canal component and a deeper lying component which may be either a so-called membrane bone, or such a bone fused with a so-called primary ossification. The primary ossification may be wholly wanting, and perhaps the canal component also. Furthermore the canal component may be found entirely separated from the underlying bone, may be found fused simply with an underlying membrane component, or may be fused with such a component and with a so-called primary ossification, which latter ossification alone is traversed by the

semicircular canal. The canal component, apparently always united with the underlying membrane bone, may as a so-called dermal bone, be found fused with other, adjoining dermal bones; while the primary ossifications may be fused with other adjoining primary ossifications (Ctenodus), or with such ossifications and the intercalar (Polypterus). It is the primary part of the bone, and not its 'Deckenknochenanteil' that gives articulation to the hyomandibular."

Throughout the discussion he does not give any reason for calling this bone the squamosal. The term squamosal signifies a homology with the squamosal of the Tetrapoda, which only a part of this compound bone of the fishes has. According to the researches of Thyng (1905) on the squamosal bone of the Tetrapoda, some of the criteria for the establishment of its identity throughout the series were as follows: "The term squamosal, including its various forms, was first applied to an element in the human skull which later fuses with others to form the temporal bone. Hence in applying the term to the lower groups the laws of nomenclature demand that it be given to that element which is the homologue of the squamosal in man. It is also evident that all possible criteria should be utilized in settling these homologies, not alone those of adult relationships and articulations, but those of development as well. . . .

"The development of the mammalian squamosal shows it to be a membrane bone which overlies the otic capsule and is at first intimately connected with the incus (quadrate) by a dense and fibrous stroma. Hence it must be concluded that close association with the quadrate (incus) and the otic capsule is the primitive relation of the squamosal, and therefore, the most important criterion in ascertaining its homology in the non-mammalian vertebrates."

Comparing the above with the statements of Allis, it is clear that the only bone in the fishes which may be compared to the mammalian squamosal is that dermal ossification which overlies the otic capsule above the lateral semicircular canal. The question of connexion with the underlying primary ossification is secondary, as is also that of the quadrate, for in the fishes the quadrate is separated from the cranium by the hyomandibular. The true squamosal would therefore, be the dermal ossification, described by Allis as lying above the cartilage of the wall of the lateral semicircular canal; it has nothing to do with the articulation of the hyomandibular and is, in the fishes, connected with the lateral line osseous canal. The primary ossification underlying it is the pterotic ossification of Parker (1873) and is just as much a center of ossification of the otic capsule as are the other periotic ossification centers of the mammalian petrosal portion of the temporal bone, although no center has been found corresponding in position to the pterotic center of the otic capsule of the fishes.

Schleip (1903) gives a detailed description of the ossifications in the region of the lateral semicircular canal wall in *Salmo* and follows Gaupp in his nomenclature, naming parts derived from membrane and the lateral line ossification,

the dermosquamosal parts, and those derived from perichondrial ossification the autosquamosal parts. His figures are clear and easy to understand. The outer perichondrial lamella (for there are two, one on the outer perichondrium of the wall and one on the inner) is strongest where it is unprotected by the dermosquamosal. In the younger stages the dermosquamosal was separate from the autosquamosal, but gradually the parts become intimately fused. He cannot say which of the two ossifications appeared first. Toward the posterior end of the roof of the lateral semicircular canal, the muscle fibres at the insertion of the levator operculi ossify and fuse with the perichondrial lamella. The articular surface for the hyomandibular ossifies later.

In the 32 mm. *Amiurus*, the two elements described by Schleich for *Salmo*, are present above the lateral semicircular canal. The dermal ossification contains the lateral line canal ossification and is partly fused with the perichondrial lamella (Fig. 31). Toward the middle line of the cranium the inner end of the dermal ossification is separated from the cartilage of the otic capsule by fibrous connective tissue and connects by suture with another dermal ossification which forms the margin of the median posterior fontanelle (Fig. 3). By fusion with the otic perichondrial ossification (Fig. 31), the dermal ossification loses its identity as a discrete ossification, as does the squamosal element of man when it fuses with the underlying periotic bones. Despite the fact that it is not related to an otic ossicle, I think that this dermal ossification overlying the roof of the lateral semicircular canal of *Amiurus* is the homologue of the mammalian squamosal. This homology however, does not apply to any other part of the compound bone. The perichondrial ossifications are formed around a center of ossification peculiar to fishes and called by Parker (1873), the pterotic ossification. As in *Salmo*, the fibres at the dorsal end of the levator operculi muscle have ossified and form a crest connected to the outer perichondrial lamella and extending posteriorly above the hyomandibular. At the posterior end of the roof of the lateral semicircular canal, the ventral arm of the post-temporal ossification projects in beneath this crest (Fig. 3). The dorsal arm of the same ossification lies behind the crest of the epiotic ossification and above the perichondrial ossification on the outer surface of the roof of the posterior semicircular canal.

Posterior to the hyomandibular articular surface on the dorso-lateral face of the lateral semicircular canal wall, the opercular-mandibular lateral line canal ends at this stage. The lateral line canal in the squamosal sends down a tubule which opens immediately above the dorsal end of the opercular-mandibular canal and eventually unites with it as in the adult (Fig. 11). The canal passes from the squamosal into the post-temporal, but before entering the latter, the osseous canal enclosing the sensory canal, is independent (Fig. 3). There is also a short interval between the end of this canal ossification and the post-temporal, where the canal lies unenclosed in connective tissue.

In certain regions of the roof of the lateral semicircular canal, the cartilage has been resorbed, as the foramina left in the chondrocranial roof show (Fig. 3), and the dermal ossification together with the lateral line ossification forms the protecting roof. The cavum of the inner ear and that of the lateral osseous canal are separated by the perichondrial ossification of the inner surface of the resorbed wall (Fig. 31). In the 60 mm. stage, endochondrial ossification has appeared in some regions between inner and outer lamellae, so that the space formerly occupied by cartilage is now filled with osseous trabeculae, just as in the more anterior sphenotic region (Fig. 33). Toward the posterior end of the roof of the lateral semicircular canal, the perichondrial lamellae, both inner and outer, are present in the 32 mm. stage (Fig. 31).

The ossification of this region of *Amiurus* agrees with the descriptions of Schleip, Gaupp, Allis and others for the teleosts, but the name squamosal employed by them should not be used alone in naming this compound bone. A squamosal element is present, but the name cannot be applied to the whole bone, as it consists of a pterotic ossification with a squamosal element added (Fig. 31); it is more like, but not completely in agreement with the mammalian temporal.

The epiotic ossification (Figs. 3, 38), or the ossification around the dorso-posterior wall of the posterior semicircular canal, has been described by various authors as a perichondrial ossification. In the teleosts it is connected to the post-temporal ossification of the shoulder girdle by a ligament which ossifies in connexion with the outer perichondrial lamella. In places the cartilage is resorbed and the lamellae form the wall. It is homologous with one of the centers of ossification of the periotic cartilage of man.

This ossification is well developed in the 32 mm. *Amiurus*. Inner and outer osseous lamellae appear in the perichondrium of the dorso-lateral and posterior walls of the posterior semicircular canal. The ligament which connects the outer lamella to the post-temporal is just beginning to ossify (Fig. 38). The posterior dorsal part of the cavum for the posterior semicircular canal is filled with osseous trabeculae continuous with the inner lamella. There is no resorption of cartilage at this stage.

At the 60 mm. stage, the perichondrial lamellae are much thicker and cover more surface. The outer lamella has extended ventrally on the wall of the semicircular canal so that it meets the ascending exoccipital ossification. Near the anterior end of the posterior semicircular canal roof, the cartilage has disappeared and the outer lamella alone forms the wall.

*The occipital region.* This part of the cranium has grown considerably since the condition described for the 10 mm. larva. The cartilage forming the posterior margin of the posterior fontanelle has grown forward and, together with the medial edges of the otic capsules, forms the synotic tectum (Fig. 3). There are ossifications on both the inner and outer perichondria of this tectum, which have been described in other teleosts as the centre of the supraoccipital

bone. The morphology of this bone will be discussed under the adult description. Sagemehl (1891) claims that the supraoccipital of the adult is a new formation in the teleosts and is not found in the ganoids nor in the dipnoi, and that it is the result of a fusion of one or more vertebra with the protometameric cranium.

In *Salmo* (Schleip), paired parietalia are present and form discrete bones in the adult. In the larva they develop as dermal sheets dorsal to the otic capsules, fused anteriorly to the frontals, laterally to the squamosal element of the squamoso-pterotic, and medially to the anterior ends of the supraoccipital. They are separated from the cartilage of the otic capsule by fibrous connective tissue.

In *Amiurus* there are a pair of such dermal ossifications in the same region and having the same histological relations. These ossifications are fused medially with the perichondrial ossification on the margin of the posterior fontanelle (Fig. 34). Despite this fusion with the perichondrial ossification, these dermal ossifications are comparable to those of the parietalia in the developing *Salmo*. The adult cranium shows that these ossifications do not persist as discrete bones as they do in *Salmo* and other teleosts. Laterally they are connected with the squamosal by a thin stroma of fibrous connective cells (Fig. 3) and anteriorly are continuous with the frontalia (Fig. 3). They have no lateral line relationships.

The details of the developing supraoccipital ossification have been described by Schleip for the salmon. The main part of this ossification, according to this author, develops as inner and outer lamellae in the perichondrium of the synotic tectum. The median dorsal fibrous septum between the dorso-lateral muscles of the two sides of the body ossifies as a vertical osseous plate above the outer lamella and connected with it. It supports at its dorsal end a horizontal osseous sheet developed from the fibrous connective tissue between the muscles and the corium. He calls it the *spina occipitis*. Both inner and outer osseous lamellae extend forward on the margins of the fontanelle anterior to the synotic tectum and are connected with each other by a transverse fibrous sheet which later ossifies and forms the roof of the cranium in this region. Schleip maintains that this fibrous sheet was originally part of the chondrocranium whose ontogenetic history has become shortened.

In *Amiurus*, at the 32 mm. stage, the synotic tectum, as remarked above, is well developed. Inner and outer osseous lamellae are present in its perichondrium (Fig. 34). The *ramus lateralis accessorius facialis* and the jugular vein of each side are enclosed in a canal formed by this perichondrial ossification along the posterior margin of the fontanelle. This canal has its anterior end at that point where the nerve and vein extend dorsally from the brain, medial to the anterior end of the posterior semicircular canal. In the 10 mm. larva, this nerve and vein lie dorsal to the cartilage of the roof of the posterior semicircular canal. After that stage was passed the cartilage below the nerve

and vein has been resorbed and the perichondrial osseous lamella forms the floor of the canal in which they lie in the 32 mm. stage. The outer perichondrial ossification, together with the parietal ossification, forms the roof of the canal, while the cartilage of the synotic tectum forms its lateral walls.

Near the anterior end of the otic capsules, the perichondrial lamellae on the margins of the fontanelle interdigitate with the frontalia (Fig. 3). There is no lateral line ossification anywhere near the vicinity of the developing supraoccipital.

The spina occipitis element of the supraoccipital is developed from the ossification of the fibrous sheet between the dorsal anterior muscle segments and the connective tissue on the dorsal surface of these (Fig. 29), as in Salmo. Near the anterior end of the spina occipitis the dorsal dermal sheet is very broad and extends laterally above the anterior ends of the body muscles (Fig. 3). The connexion of this sheet with the outer perichondrial lamella is affected by numerous osseous trabeculae. The interval between the dermal sheet and the perichondrial ossification gradually becomes greater more posteriorly, and the trabeculae become limited to the apex of the occipital arch (Fig. 29).

The dorso-lateral sides of the occipital arch are embraced by a pair of osseous plates, posterior to the otic capsules and separate from the cartilage of the arch by fibrous connective tissue (Fig. 29). These plates enclose the neural arch of the third vertebra which ensheathes the posterior end of the occipital arch and are fused with the perichondrium of the former farther posteriorly. These may be the representatives of an ossification comparable to the proatlas of the reptiles.

*The maxillary region.* The premaxillary ossification lies in the same place as in the younger stage and differs only in its extent and in the greater number of teeth attached to the ventral surface (Fig. 4). The maxillary ossification is larger, and, as before, forms a case for the proximal end of the maxillary barbel cartilage. It is attached to the lateral surface of the palatine cartilage, (Fig. 4).

*Mandibular and suspensorial apparatus.* The palatine cartilage has persisted to a great extent, but there are regions anterior to its articulation with the ectethmoid where the perichondrium has ossified and small osseous processes of bone project from its periphery (Fig. 22). The anterior end of the cartilage is large and spherical, tapering posteriorly as in the younger stage (Fig. 4), and it is flattest at the place of contact with the ectethmoid process. A small knob of cartilage projects posteriorly from its anterior dorsal surface, to serve as a support for the beginnings of the lacrimal (Fig. 3). Posterior to the articular surface the palatine is held in position by a pair of muscles which extend from the ethmoid cartilage and are fastened to its ventral and dorsal surfaces respectively (Fig. 39). Schleip ('03) says that the palatine of the salmon and trout is a mixed bone and that it has both perichondrial and dermal ele-

ments entering into its composition. In the ganoids (Van Wijhe, 1882) there is a dermopalatine below the perichondrial autopalatine which, in *Spatularia* (*Polyodon*), is attached to the maxillary and in *Polypterus* to the ectopterygoid. No such bone or ossification occurs in *Amiurus*.

The pterygoquadrate cartilage is larger than in the younger stage and the pterygoid part forms the middle of an osseous sheet, which extends ventrally beneath the cranium and posteriorly below, medial to Meckel's cartilage (Fig. 5). This is the centre of the metapterygoid bone of the adult. The quadrate is ossified along its ventral margin and is continuous dorsally with the ossification around the ventral and anterior edges of the hyomandibular cartilage. The posterior edge of this ossification is raised slightly above the surrounding parts and encloses the superior part of the operculo-mandibular canal of the lateral line; it is the anlage of the preopercular bone which has these relations in the adult. The hyomandibular branch of the facialis issues through this ossification, immediately below the anterior edge of the hyomandibular cartilage. This whole region, except for the preopercular part, was preformed in cartilage in the younger stage, the latter part having become secondarily attached to the perichondrial ossification of the hyomandibular. The dorsal part of the hyomandibular cartilage persists and abuts against the lateral surface of the otic capsule in the same region as in the younger stage. The opercular knob on its posterior face is larger and furnishes articulation for the thin plate-like operculum (Fig. 5). The interoperculum lies at the ventral end of the latter, between it and the mandible.

The centre of the dentary bone appears on the lateral surface of Meckel's cartilage and at this stage is distinct from the cartilage (Fig. 25). Teeth are attached to the dorsal anterior surface of this ossification (Fig. 5). A lateral line ossification, which has arisen independently around the mandibular lateral line canal, is attached to its ventral surface and is perforated for passage of dermal tubules of the canal. Meckel's cartilage lies in a groove on the medial surface of this ossification. In the 60 mm. stage perichondrial ossification has appeared on the surface of the cartilage and is connected by osseous trabeculae with the dermodentary (Fig. 24). The cartilage at the anterior end of the jaw has been resorbed where the symphysis takes place and the ossification here, although usually fused with the dentary, has been compared by Van Wijhe to the mento-Meckelian bone in the ganoids. He says (1882) that this bone is distinct in *Polypterus* and *Amia* and that it is fused with the dentary in *Lepidosteus*. The dentary is present as a dermal bone only, in all of these forms. In *Salmo* (Schleip 1903) the dentary is made up of the same elements as in *Amiurus*. McMurrich (1884b) recognized the elements which make up this bone in *Amiurus*.

The posterior end of Meckel's cartilage is covered by a perichondrial ossification, the centre of the articulare, which furnishes the surface for articulation with the quadrate. There is no independent ossification on the top of the

coronoid process corresponding to the autocoronoid of the ganoids (Van Wijhe, 1882). The angulare, or possibly the goniale, is represented by a small dermal ossified sheet ventral to the articulare. The lateral line canal leaves the dentary at its posterior end and extends ventral to the articulare and thence into the preopercular. In the ganoids the articulare is formed in the same manner as in *Amiurus* and has been called the autarticulare (Van Wijhe, 1882), but has a dermarticulare attached to it as an independent bone. In *Salmo* (Gaupp, 1906) the articulare is developed from two such elements, the latter containing the lateral line canal.

#### THE ADULT SKULL

McMurrich (1884) has described the cranium of the adult *Amiurus catus*, but his description and figures are incomplete and could not be used to supplement the points brought out in the first part of this paper. Other authors have made passing reference to the cranium of the Siluroids in general, but none of them give a specific description of the osteology of any one species from the point of view adopted in this paper. Pollard (1895) gives several figures of the chondrocrania of some of the South American forms, with a brief general description of each, but no reference is made to their osteology. Herrick (1901) notices the topographical relations of the cranial bones of *Amiurus melas* in his discussion of the cranial nerves.

The cranium of the adult *Amiurus nebulosus* (*catus*) is more depressed and flattened than in the later larval stages. The ossifications laid down in the 32 mm. stage have invaded and replaced the cartilage in many parts. There is however, more cartilage remaining in the adult cranium than McMurrich (1884b) noted (p. 271): "Very little cartilage remains in the skull, the anterior portion of the ethmoidal cartilage alone remaining unossified." I find considerable cartilage present in the floor of the cranium posterior to the ethmoid region, between the otic capsules (Fig. 7), and in the walls of the semicircular canals. The posterior instead of the anterior part of the ethmoid region remains unossified as the internasal septum, and will be discussed with the supraethmoid bone.

The fontanelles of the roof are well described by McMurrich (p. 270). My description of them is more complete, as I have traced their formation from the younger stages and have followed the changes which have resulted in their restriction to the median region of the roof. The ossification which divides them into anterior and posterior fontanelles (Fig. 10), is formed around the epiphysial bar of the larval chondrocranium. Most of the bones of the dorsal surface of the cranium have a delicate sculpturing.

*The supraethmoid* (Figs. 6, 7, 10). This bone in *Amiurus* has been described by McMurrich (1884b), as the 'mesethmoid.' This name implies that the bone is developed within the ethmoid cartilage and not around it, as has been shown for the larval stages. In development, the bone arises from der-

mal and perichondrial ossifications. Allis (1910) has described the bone in this region of the Loricati as the 'supraethmoid'; Sagemehl (1884), a dermal bone in this region of *Amia* as the 'ethmoid'; Parker (1873) and Gaupp (1906) as the 'supraethmoidale,' in *Salmo*; and Gegenbaur (1878), as the 'ethmoideum medium,' in *Alepocephalus*. These various terms have been used to a greater or less extent by other investigators, without regard to the significance of the terminology used. I have used the terminology of Parker and Gaupp as it applies better to the bone in *Amiurus* than any of the other terms. Very few of the authors who describe the morphological relations of the bone have studied its development and earlier histological relations; those who have agree that, in most teleosts, this bone has two parts, dermal and perichondrial, respectively. In the ganoids, as represented by *Amia* (Sagemehl, 1884), the dermal element alone is present in the same position as that element in the teleosts. A comparison of *Amiurus* and *Amia* will be made later, after this bone in the former animal has been discussed. In some of the teleosts, the dorsal surface of this bone is very rugose and is covered with numerous spines. It is usually an unpaired bone, its diverging posterior edges interdigitating with the frontals.

In *Amiurus*, the supraethmoid is the terminal bone on the dorsal surface of the cranium (Fig. 10). Its dorsal surface is slightly concave toward the posterior margin where it forms the anterior margin of the anterior fontanelle (*a.f.*). There are no spines on its dorsal surface, which is covered with fine ridges radiating from the margin of a notch (*eth. n.*) in the median anterior edge of the bone. Lateral to this notch, which is semicircular in outline, the bone sends out two cornua, which form the antero-lateral edges of the bone, and are the result of growth anteriorly of dorsal and ventral dermal ossifications from the ethmoid cornua of the 32 mm. larva, at which stage the ossifications are not present, although they begin to develop in the 60 mm. stage. They fuse with each other anteriorly, forming the sharp anterior margin of the cranium and the anterior wall of the nasal fossa (*n.f.*). They enclose a space which extends toward the middle line as far as the perichondrial part of the bone (Fig. 7). The ventral sheet extends posteriorly on the ventral surface of the cranium for a very short distance (Figs. 6, 16). The extent of this ossification can be seen only by removal of the premaxillary bones, which are closely connected to its ventral surface by tough fibrous ligamentous tissue. The anterior margin of the vomer (*Vo.*) interdigitates with the ventral ossification, and upon removal of it, several spicules from the parasphenoid (Fig. 7 *ps.*), are also visible in contact with it.

The parasphenoid lies ventral to a broad surface of cartilage (*eth.*) which forms the posterior ventral floor of the internasal septum. In a longitudinal section through this region (Fig. 7) the relations of the ossifications to the cartilage are well brought out. The ossification, which in the 32 mm. stage forms a perichondrial layer in contact with the superficial dermal ossification, has

now penetrated the cartilage, which in the adult is entirely ossified in the anterior region. A transverse section through this region of the 60 mm. stage shows the beginning of the invasion of the cartilage by the bone, both dorsally and ventrally. The posterior margin of the internasal septum persists as cartilage (Fig. 7). It extends dorsally on the ventral surface of the dermal ossification as far as the interdigitation of this with the frontals. Ventrally it extends as the floor of the cavum cranii as far posteriorly as the orbitosphenoid (O.S.). This is opposed to McMurrich's statement that the anterior end of the ethmoid plate of the larva remains unossified in the adult.

Anterior to the olfactory foramen, the supraethmoid and the ectethmoids of each side interdigitate in the wall of the nasal fossa. Comparison with the condition of this region in the 32 mm. larva (Fig. 3), shows that the ossifications of the supraethmoid and the ectethmoid are perichondrial, and are developed on the outer wall of the massive internasal septum. The jagged suture between the two bones extends dorso-posteriorly as far as the frontal-supraethmoid suture (Fig. 10) and ventrally as far as the vomerosupraethmoid suture (Fig. 6). The ectethmoids are in contact with the edges of the ventral surface of the supraethmoid and curve posteriorly from it on the surface of the ethmoid cartilage (Fig. 16). McMurrich (1884) says that the supraethmoid interdigitates posteriorly with the orbitosphenoid, and, as my figures show, this is effected by posteriorly extending spicules of the perichondrial ossification on the ventral surface of the ethmoid cartilage, as the main parts of the two bones under consideration, are widely separate (Fig. 16).

Comparison of the median section of this region of *Amiurus*, with that of *Amia*, (Sagemehl, 1884), shows several important differences. The solid cartilage characteristic of the ganoid internasal region is present in *Amia*, and there are no ossifications in it. The ethmoid is a dermal ossification and lies near the dorsal anterior end of the massive internasal septum. The cartilage beneath this ossification continues posteriorly as the solid tegmen cranii, whereas in *Amiurus*, the posterior margin of the internasal cartilage ends dorsally at the anterior end of the frontals. There is no perichondrial ossification in this region in *Amia*. The premaxillary bone abuts against the ventral surface of the anterior end of the cartilage, there being no intermediate ossification, such as is found in *Amiurus*; nor does the vomer come in contact with the ethmoid, but, since the ethmoid of *Amia* is comparable to the dorsal part of the dermo-supraethmoid of *Amiurus*, this condition is not remarkable. The ossifications surrounding the ethmoid plate of *Amiurus* have invaded the cartilage, while all the ossifications in this region of *Amia* are dermal. That the cartilage has not entirely ossified in *Amiurus* is evidence that it has advanced but little farther in its osseous development than has *Amia*.

In the Characinidae (Sagemehl, 1885)—another of the lower teleost families, which in American piscine classification (Gregory, 1907), is closely allied to the siluroids as an offshoot from the lower branches of the teleost stock—

the ethmoid region is comparable, to a great degree, with the condition of *Amiurus*. The internasal septum, except in some of the very lowest genera of the family, has the same relations as in *Amiurus*. The vomer is usually more massive and extends ventrally in between the ethmoid (Sagemehl) and the cartilage. According to Sagemehl, the ethmoid has a double origin as in *Amiurus*, the amount of ossification varying from the Amioid condition to complete ossification of the internasal cartilage. In speaking of the ventral extent of the ethmoid in this group, he hoped that further investigations would justify his conclusions that such a condition did exist in other teleosts.

In the Cyprinoids (Sagemehl, 1891), there is more or less invasion of the cartilage of the internasal septum by bone, but none of the species have proceeded as far as *Amiurus* in this respect. In this family the ossification around the ethmoid cartilage has extended on to the ventral surface and is here in contact with the vomer. Concerning this region Sagemehl says: "In Folge dieses Verhaltens können wir bei Cyprinoiden an jedem Ethmoid zwei Theile unterscheiden: eine dünne Knochenplatte, die annähernd dem ursprünglichen Deckknochen entspricht und die lateral die Nasengrube überdacht, und eine von dieser Platte nach unten absteigende mehr oder weniger breite, aus spongioser Knochensubstanz bestehende, vertikal gestellte knöcherne Wand, welche die beiden Nasengruben von einander scheidet, und die durch Knorpelsubstitution entstanden ist."

This condition is also true of *Amiurus* as shown in an earlier part of the discussion. Hence the degree of ossification in the ethmoid region of the Characinidae, Cyprinidae and Siluridae affords another factor for grouping them together.

Of the Loricati (Allis, 1910), *Trigla* has a part of the internasal septum invaded by bone, but in none does the dorsal ossification, either dermal or perichondrial, extend over the anterior end of the cranium. In *Salmo* and most of the other teleosts, the ossification is entirely dermal and has no perichondrial element connected with it, repeating the condition found in *Amia*. From the above comparisons I think that, of all the lower teleosts, *Amiurus* has the largest amount of ossification in this region and the steps in the formation of it show that it is both dermal and perichondrial in origin. The former is the first of the two ossifications to appear.

*The ectethmoids.* Each of these is developed around the ectethmoid process of either side. In the discussion of this region of the younger forms, the changes which have taken place have been described and the beginning of ossification in the 32 mm. larva has been noted. Perichondrial ossification had just begun at that stage, while the large membranous sheet attached to the lateral edge of the cartilaginous ectethmoid process had already ossified and extended posteriorly above the orbit. In the 60 mm. larva, perichondrial ossifications have appeared on both the dorsal and ventral surfaces of the cartilage which

forms the floor of the nasal process and the basal part of the process. The ossification of the dorsal surface unites with a descending perichondrial wall from the ventral surface of the roof of the internasal septum and forms the olfactory canal. Thus, in the adult, there is no cartilaginous floor in the nasal fossa, but it is formed by the premaxillary bone and tough connective tissue. In spite of all the perichondrial ossification which has taken place in this region, the articular surface for the palatine and a small strip ventral to it remain uncovered (Fig. 16). This cartilage lies between dorsal and ventral ossifications of the ectethmoid anteriorly, but posterior to the articular surface these parts unite (Fig. 16). The ventral ossification interdigitates anteriorly with the vomer, and, at the very edge of the cranium, with the supraethmoid (Fig. 6). Further contact between the ventral ossification of the ectethmoid and that of the supraethmoid is prevented by a wide expanse of cartilage visible upon removal of the vomer (Fig. 16). This figure also shows the distance between the ectethmoids of the two sides and the very regular edge that each has. They are also separated from the orbitosphenoid (OS.) by cartilage.

Posteriorly and above, the dermal ossification attached to the margin of the bone is indistinguishably fused with the perichondrial ossification surrounding the foramen orbito-nasale (Fig. 10). This dermal ossification is a very pronounced process projecting at right angles from the cranial wall. Its medial end is continuous with that part of the bone which, with the orbitosphenoid, forms the upper and lower margins of the orbital foramen (Fig. 20). These are the main features that distinguish the bone. Its dorsal surface is covered with small ridges which radiate from the center. There are also numerous nerve foramina for twigs of the ophthalmicus superficialis trigemini, but none of these are connected with a lateral line canal as McMurrich (1884b) stated, because no such canal is included in the ectethmoid. The posterior margin of the lateral process is continuous with a similar one on the margin of the frontal of the same side. The inner surface of the bone is covered with a thin layer of cartilage (Fig. 7).

Cuvier (1828) called this bone the 'frontal anterieur' and described it briefly in the perch. In his diagnosis, he said that it enclosed the olfactory nerve, was not entirely ossified, and had an articular surface for the palatine and maxillary bones. The suborbitals were attached to its lateral surface by ligamentous tissue. Except for the connexion with the maxillary, this description would apply in a very general way to the ectethmoid as described in this paper. Stannius (1854) used the terminology of Cuvier in describing this bone in the teleosts, and stated that it was one of the marginal bones of the first and second head segments.

Huxley (1864) remarked this bone as a development around the ectethmoid process in *Esox*, and, though calling the ossification, the prefrontal, he stated that it was comparable to the lateral mass ossification of the ethmoid bone of human anatomy. Vrolik (1873) followed Huxley in using this name. Its

synonymy may be found, in common with that of the other cranial bones, in tables given by Owen (1848), Vrolik (1873), and Starks (1901). Vrolik very briefly describes this bone as a 'perichondrostische' ossification, that is, what is here called a dermal ossification. It is figured for the carp, *Silurus* and other teleosts, but he does not discuss it further.

In the Cyprinoids (Sagemehl, 1891) it encloses the olfactory nerve and the ophthalmic branch of the trigeminus, has an articular facet for the palatine, and is called the prefrontal. It projects very abruptly from the lateral surface of the cranium, separating the nasal fossa and the orbit. Its developmental relations are not discussed. These same relations also hold true for the Characinidae as described by the same author (1885).

Gegenbaur (1878) calls this bone the 'ethmoide laterale' or 'praefrontale' in *Alepocephalus*. He distinguishes two parts, a lateral and a medial, the latter is developed from the ethmoid cartilage and forms the inner wall of the olfactory canal. He claims that the sculpturing on the dorsal surface is arranged concentrically and that the ridges represent lines of growth. The bone does not have the extensive articulation that it has in *Amiurus*, but is limited to the cap of the ectethmoid process.

McMurrich (1884b) made two statements concerning this bone in *Amiurus*, which contradict each other. In one place (p. 277) he says that the upper surface of the bone is very irregular and has numerous foramina connected with the mucous canal system. Farther along in the same paper (p. 280), he says that there is no connexion between the ectethmoid and the mucous canal lying dorsal to it. If the first statement were qualified to mean nerve foramina, as I think he really means, there would be no confusion in interpreting his statement. Since there are canal foramina in some of the bones of this region, this qualifying statement should be made.

Gaupp (1906), in remarking upon the development of this bone in *Salmo*, calls it the 'pleurethmoidale,' introducing an entirely unnecessary term. If one standard of nomenclature is to be adopted in comparative osteology, it should be adhered to as far as possible. Anyone reading Gaupp's papers is at once struck by the flood of new and unnecessary terms throughout all of them. According to this investigator, the ectethmoid of the adult *Salmo* is a true perichondrial ossification formed around the planum antorbitale (ectethmoid process). The adult condition is the result of endochondrification and resorption, with an added ossification formed by the ligament connecting it to the palatine. The bone includes the ophthalmic branch of the trigeminus, and the anterior ossicle of the infraorbital chain of bones is attached to its lateral surface.

Allis' (1910) description of the development of this bone in the mail-cheeked fishes (*Loricati*) is given earlier in the paper, but we can compare the adult bones at this time. As was stated previously, both have perichondrial and dermal elements, although Allis claims that the latter is perichondria

rather than dermal. The olfactory nerve issues through this bone in the mail-cheeked fishes, and in *Amiurus*, the olfactory tract. Both have a foramen for the passage anteriorly of the ophthalmicus superficialis trigemini and a facet for articulation with the palatine.

*The nasals.* In the 32 mm. stage, the only ossifications in the roof of the nasal fossa of each side were those developed around the anterior ends of the supraorbital and suborbital lateral line canals. At that stage they were narrow and tubular, the more medial ossification enclosed the supraorbital and the more lateral the suborbital canal. They were connected to the surrounding bones by ligamentous tissue, there being no contact of ossifications. In the adult, the more medial of the two bones is recognized as the nasal and the more lateral as the lacrimal. The nasal (Fig. 15) is flat and covers most of the fossa roof, its concave antero-lateral margin forming the median margin of the anterior naris. The lateral line canal occupies a very limited space on the longitudinal median dorsal surface of the bone. This canal opens anteriorly by two pores, one at the tip of the bone (Fig. 11), and the other on the latero-anterior margin, posterior to the anterior naris. Posteriorly, the lateral line canal passes from the narrow posterior tip of the bone and proceeds through a mass of connective tissue before entering the anterior end of the frontal (*fr.*). The flat and scale-like appearance of the bone is the result of ossification of part of the fibrous connective tissue below the lateral line canal ossification. In outline the bone is suggestive of the nasal of *Amia* (Sagemehl, 1884), but it is not nearly as massive nor does it meet its fellow of the opposite side. The enclosed lateral line canal does not connect with that of the other side within the ethmoid as it does in *Amia*. The nasal of the Characinidae (Sagemehl, 1885) is more like that of *Amia*, and comes in contact with the ethmoid cartilage as in the latter, but not in *Amiurus*. The Cyprinoid nasal is more nearly like that of *Amiurus* than of *Amia* or the Characinids. In *Salmo*, (Schleip, 1903) the nasal develops in contact with the ethmoid cartilage and encloses a lateral line canal. In *Gasterosteus* (Swinnerton, 1902), this bone is very large and intimately connected with the ethmoid cartilage; it extends on to the ventral surface of the cranium after forming the roof of the nasal fossa, but the presence of a lateral line canal within it is not mentioned.

In the Amphibia, Reptilia, Aves, and Mammalia, the nasal bone occurs as a dermal ossification on the roof of the nasal capsule. In some mammals the cartilage of the capsule beneath this bone disappears, and a condition comparable to that of *Amiurus* results. The teleostean nasal bone is comparable, then, in a certain degree with the nasal of the higher groups. In nearly all of the teleosts however, this bone contains a lateral line canal ossification on its dorsal surface. In *Amiurus* the bone is isolated, but in most of the other forms it connects to a greater or less degree by suture with the surrounding bones.

*The lacrimals.* A single lacrimal on each side of the head forms the lateral roof of the nasal fossa (Fig. 15). Each is very small and narrow and contains

the anterior end of the suborbital lateral line canal of its side. The most anterior dermal tubule of the canal issues from the bone through its dorso-medial edge (Fig. 11). From the small central part of the bone four processes radiate, two anterior and two posterior. The antero-lateral process is slender and curves around the external margin of the anterior naris. The anterior end of the suborbital canal, after leaving the main part of the bone at the proximal end of this process, proceeds immediately to the external surface of the head. The process is closely connected by ligament to the maxillary and premaxillary bones, and to the ethmoid cornu of the supraethmoid bone.

The median anterior process of the lacrimal projects toward the middle line of the fossa roof, posterior to the anterior naris. It contains the first dermal tubule of the suborbital lateral line canal, the pore of which lies lateral to the pore of the first dermal tubule of the supraorbital canal, posterior to the margin of the anterior naris (Fig. 11).

The elongate median posterior process extends posteriorly toward the anterior face of the ectethmoid bone. It lacks a lateral line canal element. The anterior ossicle of the infraorbital series of lateral line canal bones (Fig. 15) is connected with its ventral margin by ligament. The lateral posterior process of the lacrimal lies external to the first suborbital bone, so that the suborbital lateral line canal enters the posterior margin of the lacrimal between the posterior processes. After giving off the dermal tubule described above, the canal ends by the passing to the exterior. There is one sense organ, the most anterior of the suborbital lateral line canal, contained within the lacrimal bone. The nasal bone encloses the most anterior sense organ of the supra-orbital canal.

The older writers—Cuvier, Stannius, Hallman, Wagner, Huxley and others—recognized the lacrimal bone as the anterior element of the suborbital or infraorbital series. In most of the forms studied it was the largest and gradually came to have a greater morphological significance than the more posterior elements of the series. It contains a part of the suborbital lateral line canal in most teleosts and in *Amia*, and is usually related to the roof of the nasal organ. Where its development has been studied (Schleip, 1903), it has been found to arise primarily as an ossification developed in connexion with a lateral line sense organ, and later has an osseous base formed from surrounding connective tissue. In *Amiurus*, as noted above, the lateral line element is the first to appear and the dermal part does not ossify until much later. I am satisfied that this bone has two parts as Schleip has stated, and that the dermal part may be homologized to the lacrimal bone of the higher groups. As the lateral line canal is associated with those forms which live in the water, so is the lacrimal canal found in those animals which pass most of their lives in the air. In both cases the bone develops lateral to and usually dorsal to the nasal organ and is a dermal ossification. It may have more or less connexion with the surrounding bones—nasal, maxillary, premaxillary, supra-

ethmoid, and ectethmoid—and in some of the fishes with the vomer. Allis' (1898) criterion for the homology of the lacrimal is the inclusion within it of the anterior end of the suborbital canal. In comparing his work on *Amia* with that of McMurrich on *Amiurus*, he concluded that the antorbital of *Amia* was the homologue of the adnasal (lacrimal, Author) of *Amiurus*. Since however, this bone of *Amiurus* contains the anterior end of the suborbital canal it is the lacrimal and the antorbital of *Amia* is represented by the long antero-lateral process, which has fused with the lacrimal element as it has in some other teleosts.

*The frontals.* These are the most extensive and conspicuous bones on the dorsal surface of the cranium, forming most of the roof and part of the side walls of the cavum cranii (Fig. 10). The only point of suture between the two is in the region of the original epiphysial bar. Anterior and posterior to this suture they are separated from each other by two longitudinal fontanelles, the remnants of the more extensive ones of the younger stages. Each has a raised margin on the sides of these fontanelles, thus bounding a fossa which continues anteriorly as far as the supraethmoid and posteriorly on to the dorsal surface of the supraoccipital. This fossa is filled with connective tissue and nerve fibres, and a tough membrane is stretched the entire length of each of the fontanelles. Their restriction is caused by median growth of the frontals, a process noted in its incipience in the 32 mm. stage. Earlier, however, the posterior fontanelle extended between the anterior edges of the occipital arch, but the ossification in this region has grown forward and closed the extreme posterior end of the fontanelle.

Anteriorly, the frontals interdigitate with the median supraethmoid, which forms the anterior margin of the anterior fontanelle. This interdigitation lies above the orbito-nasal foramen and is continuous laterally with that between the ectethmoids and the frontals (Fig. 10). An oblique frontal ridge, along which the adductor mandibularis muscle has its origin, extends posteriorly across the dorsal surface of the frontal from the lateral posterior margin of the ectethmoid. The frontal ridge does not extend to the posterior end of the bone, but unites with the ridge which forms the margin of the median fossa. Behind the union of the two ridges a wing of bone extends laterally to interdigitate with the sphenotic. Anterior to the ridge the surface of the bone is sculptured in longitudinal lines, which run posteriorly toward the middle line of the cranium, parallel to the dorsal margin of the ridge and extending along its anterior face. Posterior to the frontal ridge the bone is comparatively smooth.

At the anterior end of the frontal ridge the suborbital lateral line canal enters the frontal bone from the postfrontal (Fig. 11). The two bones are not in contact with each other, so that the canal crosses the dorsal surface of the adductor mandibularis muscle before entering the frontal. A dermal tubule is given off from this part of the canal as it passes from the postfrontal to the frontal.

The frontal bone extends down into the wall of the orbit, externally connecting by suture with the orbito- and alisphenoid ossifications (Fig. 20). In the anterior part of the orbit it is separated from the ectethmoid bone by a small remnant of the fused alisphenoid-ectethmoid cartilage. Posteriorly it interdigitates with the anterior end of the sphenotic bone, above the alisphenoid. On the inner surface of the *cavum cranii*, the frontal descends in the cranial wall in front of and behind the line of suture between the two frontals, but immediately below the suture this downgrowth is limited by the dorsal parts of the ali- and orbitosphenoids. Anteriorly it overlaps the orbitosphenoid and continues as far forward as the cartilage which lines the *cavum* within the ectethmoid. Posteriorly it overlaps the alisphenoid, interdigitates with the anterior margin of the sphenotic and proceeds dorsally toward the middle line of the cranium to interdigitate with the supraoccipital.

There are many minute nerve foramina and canals in the frontal bone, but none of them reach the *cavum cranii*. The largest canal is that of the *ophthalmicus superficialis facialis*, which, after issuing from the alisphenoid, sends a branch along the dorsal median wall of the orbit and is enclosed within the frontal. It continues forward within the bone, sending small twigs dorsally into the bone to the lateral line organs contained within it and also clear through the bone to the integumental sense organs above (Fig. 10). Anteriorly, the nerve passes to the dorsal surface of the bone through a small foramen, just below the insertion of the connective tissue which connects frontal with nasal.

The supraorbital lateral line canal, which starts in the nasal bone, enters the anterior end of the frontal after passing through the connective tissue between the two bones. The anterior point of ingress of the canal lies just dorsal to the foramen for the passage of the ophthalmic branch of the *facialis*. From this point its course cannot be followed externally, but must be traced by following it through a series of transverse sections, (a 60 mm. specimen was used for this). There is one dermal tubule and pore anterior to the frontal ridge on the dorsal surface of the bone. As noted above, the suborbital canal enters the frontal at the anterior end of the frontal ridge. It anastomoses with the supraorbital canal beneath the ridge and a dermal tubule extends along the posterior face of the ridge from the supraorbital canal, just before their anastomosis. The canal formed by the anastomosis continues posteriorly from the middle of the frontal ridge and thence into the sphenotic bone (Fig. 11). There are three sense organs in the canal enclosed in the frontal at points shown in Figure 11. The first and third are followed by dermal tubules, but the second, which lies just anterior to the union of supraorbital and suborbital canals is not.

This bone of the adult is the result of the ossification of the membrane above the alisphenoid cartilage of the larva. In sections through the 60 mm. larva the fibrous connective tissue surrounding the ventral surface of this membrane have ossified and appear as lamellae capping the perichondrial ossification of the dorsal surface of the alisphenoid cartilage (Fig. 32). The ossifications of

the two sides of the head have fused around the epiphysial bar, and the cartilage within it has all but disappeared. None of this ossification connecting the frontals of the two sides is perichondrial. In the adult, the cartilage has entirely disappeared from the interior of the ossification (Fig. 7) surrounding the original epiphysial bar. Anterior to this bar the frontal is thin and solid, while behind, although just as solid, the bone is much thicker. The nerve foramina in the bone are later developments and are caused by the growth of osseous trabeculae around the nerve twigs and branches. The ossification around the lateral line canal has now become an integral part of the bone.

The older comparative anatomists homologise the frontals of the fishes with those in the higher animals and based their conclusions upon topographical rather than embryological relationships. As far back in the literature as I have gone, these bones have always been known as the frontalia with, perhaps, an added adjective to distinguish them from the anterior and posterior frontalia. In practically every teleost and most of the ganoids they are the largest bones on the dorsal surface of the cranium and are usually paired. Fontanelles like those of *Amiurus* were recognized in the teleosts by Cuvier and are again referred to by Stannius (1854). In *Amia* and most lower teleost families these fontanelles are absent and the frontals are connected by suture along their entire length.

In comparison with the frontals of *Amiurus* those of *Amia* show limitations of development ventrally and internally. They cover more of the dorsal surface of the cranium than those of *Amiurus*, but they take no part in the wall of the cavum cranii, being separated from it by the solid cartilaginous tegmen cranii (Sagemehl, 1884). They do not interdigitate anteriorly with the supraethmoid because of its limited development, but their relations to the nasal bones are comparable to those of *Amiurus*. In the orbital wall, the frontal of *Amia* is separated from the orbitosphenoid and alisphenoid ossifications by cartilage. Cartilage does not extend between the frontal and ectethmoid (prefrontal, Sagemehl) as in *Amiurus*.

In the Characinidae there is a mixture of the condition found in *Amia* and that of *Amiurus*. *Citharinus* (Sagemehl, 1885) approaches the *Amiurus* type of frontal development externally, but is more like *Amia* internally, in that more cartilage persists in the side walls and the roof of the cranium than in *Amiurus*. The epiphysial bar is not enclosed by the frontals, although they meet above it. *Sarcodaces* lacks the anterior fontanelle found in *Citharinus* and the posterior fontanelle lies more between the parietals than the frontals. Internally, there is less cartilage than in *Citharinus*, but the epiphysial bar remains unossified. The other families of the lower teleosts—*Mormyridae*, *Osteoglossidae*, *Clupeidae*, *Gymnarchidae* and others—have the frontals connected by suture as far back as the parietals which are highly developed in these forms. The internal relations of the frontals have not been described for

any of these lower teleosts and it would be interesting to find out how much cartilage remains beneath them.

In the Cyprinidae (Sagemehl, 1891), the frontals have relations which closely approach those of *Amiurus*, but the anterior fontanelle is always closed in those genera figured by Sagemehl. The epiphysial bar persists as cartilage in the adult, and the frontals have not extended beneath it as they have in *Amiurus*. In none of the forms thus far mentioned have I been able to find a frontal ridge for the adductor mandibularis muscle comparable to that in *Amiurus*. The postfrontal (sphenotic, auct.) never has the dorsal extent that it has in *Amiurus*, but is always overlapped by the posterior margin of the frontal.

•In the Salmonidae, the frontals lie superficial to the tegmen cranii (Parker, 1872), as they do in *Esox* (Huxley, 1864) and take very little part in the formation of the orbital roof, probably because of the persistence of the cartilage in this region. Further discussion of the topographical relations of the frontals is unnecessary because the above shows that there is a general agreement in position throughout the whole group of teleosts.

The relations of the nerves to this bone were neglected by the older anatomists and not until Sagemehl's description of *Amia* were these studied. As in *Amiurus* twigs from the ophthalmicus superficialis facialis (Sagemehl's fifth) pass into the bone to innervate the sense organs of the lateral line canal. The Selachians have a series of foramina in this same region penetrating the supra-orbital cartilage (Gegenbaur, 1872; Wells, 1917). In the Characinidae the ophthalmic branch of the facialis has the same relations as in *Amia* and *Amiurus*. In *Amia* an anterior branch of it extends dorsally through the cartilage and frontal at the anterior end of the orbit. In the Characinidae, Cyprinidae and *Amiurus*, this branch passes to the dorsal surface of the cranium through the frontal alone. In *Amiurus* it lies free in the orbit in the younger stages and its enclosure within the frontal is accomplished by growth ventrally from the frontal of osseous spicules which finally enclose the nerve within a canal.

Von K  lliker (1850) was one of the first to work out the histological development of the frontals. Up to his time there was a controversy between those who thought that the bone was developed from membrane and therefore comparable throughout the whole vertebrate series, and those who held that in the Aves and Mammalia it was developed from cartilage. Reichert (1849) was responsible for the latter statement and von K  lliker took it upon himself to settle the controversy by histological and chemical analysis. The chemical analysis of the bone showed that it did not have a trace of the chondrin common to the bones developed from cartilage. As a result of his work he came to the conclusion that the frontal bone throughout all the groups was developed from dermal connective tissue and had nothing to do in development with the underlying cartilage. Subsequent researches on the development of the bone have borne out his statement. Gegenbaur (1864) and Hertwig (1876) both agree that originally the frontal bones were dermal scales which, in the course of

phylogenetic changes, have sunken to their present position and fused into a solid osseous mass. *Acipenser* typifies the indifferent stage where the scales have not yet formed bones.

The supraorbital lateral line canal is usually associated with the frontal bone in the ganoids and teleosts, and there are many or few pores on the dorsal surface of the bone connected with it. Vrolik (1873), in his general description and in the conclusions of his work on the development of the frontal bones of teleosts, states that the frontal bone is developed primarily to protect the canal. This has since been refuted by those who have worked out the developmental relations of the canal and the bone. The ossification around the canal is at first entirely separate from that of the main part of the frontal (Klaatsch, 1895, Schleip, 1903, and others). In *Amiurus*, as remarked earlier in this paper these have been noted as separate ossifications.

In brief, the frontal bones of the teleosts are paired ossifications arising from fibrous connective tissue. They may lie above a solid cartilaginous roof or they may form an integral part of the cranial roof. Anteriorly they usually interdigitate with the supraethmoids and the ectethmoids, and are separated from the nasal bones by a connective tissue bridge across which each supraorbital canal extends to enter the frontal. Posteriorly they usually interdigitate with the parietals, but in the Siluroids the parietals are not present as discrete ossifications, so they interdigitate with the supraoccipital. There is commonly a fontanelle between the posterior ends of the bones, and in *Amiurus* and some few of the Characinidae there is an anterior fontanelle as well. The frontals overlap the orbitosphenoid and alisphenoid bones in the wall of the orbit, both internally and externally in those forms where ossification has proceeded very far. They also contain foramina and canals for the passage of the ophthalmic branch of the facialis to the integumental sense organs on the dorsal surface of the head and to the lateral line canal organs within the supraorbital canal.

*The infraorbitals.* This series includes the lacrimal described above, and another group of bones which extend from the posterior margin of the lacrimal below the eye, so that the most postero-dorsal bone of the series, the postfrontal, is attached to the frontal ridge, posterior to and above the eye (Fig. 15). The whole series is made up of three suborbitals, two postorbitals, and the postfrontal. These bones enclose the infraorbital or suborbital lateral line canal and are developed primarily for its protection. None of the bones unites by suture to its neighbors, but connexion is effected by ligamentous tissue and the fascia enveloping the muscles of this region.

The three suborbitals are the most slender and reed-like of the entire series. They lie deeply embedded in the connective tissue anterior and posterior to the ectethmoid process, two being anterior to the process and the third just behind it. The first is the smallest of the trio and the second is next in size. Both of these have practically the same diameter as the enclosed lateral line canal.

None of the suborbitals are sculptured. The third suborbital lies below the eye and is nearer to the cutis than the other two. It lies above the fascia of the anterior fibres of the adductor mandibularis muscle.

The two postorbitals are broader than any of the suborbitals. The first curves around the posterior margin of the eye and is attached superiorly to the inferior end of the second postorbital. The latter is the largest and longest bone of the series and is slightly curved dorsally toward the anterior part of the orbit. Ridges run on the anterior surface of the bone parallel to the course of the enclosed canal. Both postorbitals are firmly embedded in the fascia of the adductor mandibularis and the dilator operculi muscles, some of their fibres having their origin along the ventral surface of these bones.

The most dorsal and posterior bone, the smallest of the series, is the postfrontal. It lies dorsal to the superior end of the second postorbital, and like it, is embedded in the muscle fascia. This bone is not as flat as the others, the posterior margin being grooved, the margin of the groove projecting dorsally. The posterior end of the suborbital canal, which passes through the other bones of the chain lies within this groove. The anterior face of the bone is sculptured. As remarked above, the postfrontal is connected with the frontal by ligamentous tissue.

The principal morphological feature of this series of bones is their relation to the suborbital lateral line canal. From the lacrimal bone this canal extends through the infraorbital chain into the frontal. As it passes from one bone to the other it lies within the connective tissue which joins the two bones, and at these points between the bones, from lacrimal to frontal, a dermal tubule extends from the main canal to the surface of the integument where it opens by a single pore. There are five of these dermal tubules and pores between the posterior end of the lacrimal and the junction of the suborbital canal with the supraorbital in the frontal bone. There is no tubule between the lacrimal and the first suborbital nor between the postfrontal and the frontal. There is a sense organ in each bone of the series (Fig. 11).

The development of these bones has been studied by Klaatsch (1895) and Schleip (1903). The former claims that all the bones develop from osteoblasts which proliferate below each sense organ of the developing system. He maintains that all the bone connected with a canal arises from these same osteoblasts. Schleip derives the lateral line containing element proper from these osteoblasts, but goes no further. Allis (1898) thinks that true dermal elements are present, comparable to those which give rise to such bones as the frontal, supraethmoid, and other dermal bones of the head. In the development of *Amiurus* the bones begin as Klaatsch and Schleip have stated, and in the 32 mm. stage the canals are enclosed in tubular bones, all of which are close to the periphery of the canal wall. The rest of the bone is developed from the ossification of the fascia in the immediate region of these tubular bones, but I have not been able to trace the derivation of the osteoblasts which cause the ossification.

The number and size of these bones vary in the different families of ganoids and teleosts, but their position with regard to the eye and their relation to the suborbital lateral line canal are constant. The older comparative anatomists recognized them as the suborbitalia, or frequently as the infraorbitalia, setting off the anterior bone of the series as the lacrimal on account of its size and relation to the nasal capsule: Van Wijhe (1882) remarked in a foot-note, that the developmental relation of these bones to the suborbital canal was a good character for homologizing the bones in the different groups. The nomenclature used in this paper is based upon that used by Allis (1898) in *Amia*. McMurrich (1884b) found six bones in the series in *Amiurus*, but did not differentiate nor make a detailed study of any of them. He says there are pores in these bones for the passage of more or fewer mucous canal tubules. In reality, there are no pores for the passage of such tubules because these leave the canals between the bones, issuing through the connective tissue in this region. Collinge (1895) has given a partial description of the relations of the suborbital lateral line canal to the infraorbital bones in *Amiurus catus*, and figures no tubules between the lacrimal bone and the junction of this canal with the supraorbital. Gegenbaur (1878) recognized seven elements in the infraorbital chain of *Alepocephalus rostratus*, the posterior bones being situated in the muscle fascia on the dorsal surface of the cheek muscles. A dermal tubule passed to the exterior between each bone, and in the first of the series, which is comparable to the main body of the lacrimal of *Amiurus* there were a number of tubules as in the same bone in *Amia*.

Allis (1898) called the last bone of the infraorbital series in *Amia*, the postfrontal, and justifies himself in so doing, by stating that the postfrontal never fuses with the underlying postorbital perichondrial ossification and always contains a part of the suborbital canal. He states that in some members of the Characinidae, and Cyprinidae, and in Scomber, in which the dilator operculi muscle lies on the dorsal surface of the cranium, this postfrontal lies above the muscle. The postfrontal of *Amiurus* fulfills all of these requirements and hence corresponds to the same bone in the groups mentioned.

According to this view the infraorbital chain of bones is comparable to the orbital ring of the Stegocephalans and Reptiles, in which there is usually a large lacrimal anterior to the eye, a zygomatic below the eye, followed by a postorbital, above which is a postfrontal. The fact that, although the zygomatic bone is a member of the maxillary series, it never bears teeth lends some support to the assumption that it is a lateral line bone rather than dental in origin. Most older authors homologized this ring of the fishes on purely topographical relationships, to the jugal arch of the reptiles, and Bojanus (1818) called them the ossa jugalia. Gaupp (1906) makes no statement concerning this homology. Cuvier first applied the name postfrontal in the fishes to that bone which is today recognized as the sphenotic, because he thought it was the homologue of the postfrontal of the Reptiles.

According to Allis (1898), the lacrimal of *Amia* is the homologue of the first suborbital of *Amiurus*. He regarded the adnasal of *Amiurus* as described by McMurrich (lacrimal, Auct.) as the homologue of the antorbital of *Amia*, justifying his statement by saying that Collinge says that many authors call the bone by that name. Since this bone in *Amiurus* contains the anterior end of the suborbital lateral line canal, I have called it the lacrimal, and it is possible that the long anterior lateral process may be the homologue of the antorbital of *Amia*. Merely because there are six infraorbitals in *Amiurus* and *Amia*, counting the lacrimal in the latter, but not in the former, it does not follow that the members of the series are numerically homologous from the anterior to the posterior end. The criterion for homology rests upon the relation of the bone to the nasal capsule and the part of the lateral line that it contains.

*The vomer.* This bone, broad, flat, and unpaired, lies near the anterior end of the ventral surface of the cranium. It is entirely superficial to the bones which invest the chondrocranium in this region and is covered by the skin of the roof of the mouth (Fig. 6). As McMurrich (1884b) said, the bone is nail-shaped, the head of the nail is represented by the broad anterior portion and the shaft by the posterior spicules. It lacks the anterior extension common to the vomer of most teleosts, and is limited in front by the supraethmoid. The serrate line of interdigitation between these two bones extends as far laterally on each side as the ventral end of the supraethmoid-ectethmoid interdigitation. The vomer is here separated from the margin of the descending ectethmoid by a cartilaginous plate which is continuous with the palatine articular surface. Postero-laterally each side of the vomer interdigitates with the anterior edge of the ventral portion of the ectethmoids. Internal to these edges the several spicules mentioned above extend posteriorly in a series of grooves on the ventral face of the parasphenoid. The bone does not articulate with the premaxillaries and it is firmly united with the parasphenoid. The ventral ossification of the supraethmoid extends beneath it, separating the anterior part from the chondrocranium, while the anterior end of the parasphenoid cuts it off behind from the orbitosphenoid (Fig. 7). The bone itself is very thin and some of the fascia for muscle fibres of the entopterygoid muscle are attached to the postero-dorsal margins. It has no teeth and none are developed in the roof of the mouth below it. The development of the bone has been described earlier in the paper.

Since Cuvier compared this bone in the fishes to the vomer of man, it has borne this name, although many arguments have been advanced for and against this view which I will not attempt to discuss here. As it is one of the most evident bones on the anterior ventral surface of the skull in all teleosts, there has been no confusion in describing its topography. In some of the lower teleosts—*Scomber*, *Salmo*, and the *Loricati* are among the best known

examples—the vomer bears teeth and some have thought that these were an integral part of the bone. Schleip (1903) has shown that in *Salmo* the vomer develops, as in *Amiurus*, from deep-lying connective tissue beneath the chondrocranium and that the teeth arise independently. In some of the Characiniidae and Cyprinidae, the vomer is intimately connected with the cartilage of the ethmoid plate. In all adult teleosts it is unpaired, although it may arise from paired parts as in *Esox* (Walther, 1882). In some it forms a cap on the anterior end of the ethmoid cartilage. In none of the forms described up to this time has a condition wholly similar to that in *Amiurus* been found. Its limitation to the ventral surface of the cranium is not the common type of development, as there are usually anterior or lateral processes projecting for articulation with the cranial bones of the dorsal surface.

*The orbitosphenoid.* This is a large unpaired bone forming the floor and side walls of the cranium between the orbital and optic foramina (Figs. 6, 7, 16, 20). It is visible externally in the wall of the orbit, overlapped dorsally by the frontal and interdigitating anteriorly with the ectethmoid in both the upper and lower margins of the orbital foramen. This part of the bone is only a thin lamella on the cartilage which persists in the side walls of the cranium and unites with a similar lamella on the internal surface of the cartilage in the margins of the foramen.

The anterior end of the alisphenoid bone extends down in front of the optic nerve so that the orbitosphenoid is limited to the ventro-anterior wall of the foramen. In the midventral margin of the foramen it interdigitates externally with a lateral process of the parasphenoid, and the line between them extends across the ventral surface of the cranium to the optic foramen of the other side. The immediate middle part of this interdigitation is visible only upon removal of the vomer and the anterior spicules of the parasphenoid (Fig. 16). The ventral anterior end of the orbitosphenoid is separated from the laterally lying ectethmoids by cartilage. The median anterior margin lies quite far posterior to the main part of the supraethmoid, but several spicules from the latter bone extend posteriorly to it along the dorsal surface of the parasphenoid (Figs. 7, 16). The interval between the main parts of the supraethmoid and the orbitosphenoid is occupied by the ethmoid cartilage.

There is a notch on each side of the bone in the orbital wall, just behind the orbital foramen, for the attachment of the pterygoid muscles (Fig. 20). The ventral wall of the notch continues posteriorly as far as the optic foramen and forms a shelf supporting the optic nerve. The whole ventral surface of the bone is roughened by fine lines. On the median ventral part of the bone, which is closely applied to the dorsal surface of the parasphenoid, the lines run longitudinally, and on the lateral parts in the orbital walls, they radiate from a center on each side (Fig. 16).

A longitudinal section through the cranium shows the relative extent and thickness of the orbitosphenoid (Fig. 7). The dorsal posterior surface of the

bone is overlapped by the suprasphenoid and the ventral, by the parasphenoid; suprasphenoid and parasphenoid bones fusing at the posterior margin of the bone. Anteriorly the orbitosphenoid thins out and passes gradually into the cartilage of the internasal septum. The middle part of the bone has entirely ossified, but the persistence of cartilage beneath the external lamellae of the lateral parts of the bone shows that ossification does not extend uniformly through all its parts. The frontal overlaps the dorsal margin of the bone in the cavum wall and in line with the epiphysial bar region the alisphenoid and orbitosphenoid meet above the optic foramen. Considerable cartilage remains in both of these bones in this region, but between this point and the anterior end, the part of the orbitosphenoid which forms the wall of the cavum is well ossified. Below the optic foramina the orbitosphenoid-suprasphenoid interdigitation continues from one side to the other within the cavum, marking the posterior limit of the orbitosphenoid as a lining bone of the cavum cranii (Fig. 7).

The developmental relations of the orbitosphenoid have been given for the 32 mm. stage (p. 52). The perichondrial ossifications in the wall of the cranium which now form an integral part of the bone were then just beginning. From the description just above, it is evident that there is considerable cartilage yet remaining within these osseous lamellae. The ledge on the external surface of the bone, between the orbital and optic foramina, is developed from connective tissue surrounding the ventral end of the alisphenoid cartilage and the trabecula cranii, and is intimately connected with the perichondrial ossifications of these cartilages (Fig. 3). The stout median part of the bone is developed from perichondrial ossifications which have fused with each other across the anterior end of the fenestra hypophyseos (Fig. 4). In the younger stages the cerebral hemispheres lie immediately dorsal to the orbitosphenoid region, but in the adult they are quite far posterior to it, and the olfactory tract surrounded on each side by a gelatinous mass extends above it. The anterior end of the jugular vein enters the cranium through the orbital foramen and proceeds posteriorly along the dorsal surface of that part of the orbitosphenoid which forms the wall of the cavum cranii.

The earlier descriptions were confusing because of the absence of this bone in some of the lower teleosts, especially since it is absent in the perch, Cuvier's type of fish cranium. The present identity of the bone with the *ala orbitales* of mammalian anatomy is derived from the work of Hallmann (1837). He recognized Cuvier's error in naming the petrosal, the *ala magna* and hence confusing the homologies of the more anterior parts. Since the bone next in front of the petrosal in mammals was the *ala magna* of the sphenoid, and since this bone in the carp had relations corresponding to it, the name was applied. The bone in front of this was then compared to the '*ala parva*' and found to correspond, hence it was named. Agassiz (1842) and Stannius (1853) did not adopt this homology, but named the bone the *os ethmoideum*. The

name, orbitosphenoid, given to the bone by Owen (1848), is in general use at the present time.

In many of the lower teleosts, where a large interorbital septum is developed, the orbitosphenoid is lacking. Among these are Scomber, the Loricati (Allis, Gutberlet); Perca (Cuvier, Hallmann); Osteoglossum, Gonorhynchus, Chanos (Ridewood, 1904); Gasterosteus (Swinnerton, 1902); and others not referred to here.

In *Amia* (Sagemehl, 1884) the orbitosphenoid is paired and lies on the cartilage above the anterior margin of the optic foramen, separated from the bones above and in front by cartilage. In *Arapaima* (Ridewood, 1904), it is paired, but unlike *Amia*, these ossifications extend from the frontals to the parasphenoid. In those species with a medium sized interorbital septum as *Salmo* (Parker, 1872); *Alepocephalus* (Gegenbaur, 1878), and some of the Cyprinidae (Sagemehl, 1891), the orbitosphenoid is unpaired and Y-shaped, the arms of the Y extending up in the walls of the cranium and the basal part down into the orbital septum. It always lies above the anterior margin of the optic fenestra and usually the basal piece ossifies as far ventrally as the trabecula communis. In the Characinidae the bone has various gradations in structure from the U-shape corresponding to that of *Amiurus*, to the Y-shaped Salmonoid type. Of all the forms studied I think that the orbitosphenoid as found in *Homolopterus* of the Characinidae is the closest in orbitosphenoid relations to *Amiurus*. There is the same strongly ossified midventral piece, and the same general relations to the surrounding bones and to the optic nerve. The orbital foramen is also present between the orbitosphenoid and the ectethmoid of each side and considerable cartilage remains within the bone, a strip of it persisting between the frontals and upper ends of the inner surface of the bone.

Vrolik (1873) maintained that, because the orbitosphenoid is an inconstant bone and because it could be developed from either the membrane of the interorbital septum or from cartilage, that it could not be homologized throughout the different groups. The fact of its relation to the nerve foramina, its gradation in development in the lower forms all aid in proving that it was a paired bone in the ancestral teleosts, and that it was originally developed from cartilage. Cartilaginous cells are present in the interorbital septum of those forms in which the septum is decidedly primitive, a circumstance which may be taken to indicate that there has been a shortening of the ontogeny of the septum in the higher forms where the septum ossifies directly.

*The parasphenoid* (Figs. 6, 7), is a long, flat, unpaired bone extending on the ventral surface of the cranium from the supraethmoid to the anterior end of the basioccipital. Its anterior interdigitation with the supraethmoid is hidden by the vomer. The median anterior end of the parasphenoid is kept from contact with the ethmoid cartilage or internasal septum by the supra-

ethmoid (Fig. 7). The posterior spicules of the supraethmoid are inserted in grooves on the ventral surface of the parasphenoid. The anterior lateral margins of the bone, fitting tightly against the cartilage of the ethmoid plate, are separated from the ectethmoids by a narrow interval. Posterior to the supraethmoid, the orbitosphenoid is developed between the parasphenoid and the chondrocranium. In this region the parasphenoid is limited to the ventral surface of the orbitosphenoid; the arcus palatini muscles are inserted in a groove on each side of the former. The projection ventral to this groove ends posteriorly in a little knob ventral to the trigemino-facial foramen (Figs. 6, 20). At the posterior end of the orbitosphenoid the parasphenoid expands laterally to form the posterior margin of the optic foramen, interdigitating dorsally with the alisphenoid. Behind the alisphenoid the parasphenoid interdigitates with the prootic and with it forms the ventral posterior margin of the trigemino-facialis foramen. The posterior end of the parasphenoid is inserted in grooves on the ventral surface of the basioccipital.

Behind the orbitosphenoid, the parasphenoid is excluded from the floor of the cavum cranii by the suprasphenoid. In the younger stage the suprasphenoid develops on the cerebral surface of the parasphenoid and is firmly connected with it, even in the 32 mm. stage (Fig. 32). There are spaces in the floor of the cranium close behind the orbitosphenoid between the para- and suprasphenoid in the adult which show where the cartilage has been resorbed (Fig. 7), but traces of cartilage are present also. Sagemehl, in his study of the Characinidae and the Cyprinidae, did not recognize a suprasphenoid element ankylosed to the cerebral part of the parasphenoid, but described the floor of the cavum as formed by the parasphenoid. It is evident that, had he studied the development of this region, he would have identified two elements in the composition of his parasphenoid. He states that in the Cyprinidae the parasphenoid forms the posterior end of the interorbital septum when such is present. In all of the other teleosts, as *Salmo*, with a medium sized interorbital septum, the part of the septum posterior to the optic foramina and anterior to the hypophysis is formed by a Y or T-shaped suprasphenoid (basisphenoid of the usual terminology). The parasphenoid always forms the support of the basal part of the Y. In *Amiurus* there is no basal part to the Y, consequently the arms lie directly upon the cerebral surface of the parasphenoid and it is only by the study of the development of this region that the two elements are recognizable. Even in the adult the two elements are recognizable to a certain degree in the median section of the cranium (Fig. 7), where the posterior end of the orbitosphenoid and the anterior end of the prootic are enclosed by the parasphenoid externally and the suprasphenoid internally.

In those fishes which have a well developed eye-muscle canal—*Salmo*, *Scomber*, and the *Loricati*—the parasphenoid is separated from the prootic bones by the lumen of the canal, the floor and part of the side walls of which are formed by the parasphenoid. In *Amiurus* the parasphenoid is fused to the

ventral surface of the prootics (Fig. 7). The wings which extend dorso-laterally between the orbitosphenoid and the prootic, are characteristic of the teleostean parasphenoid. In some forms they lie behind the fifth nerve and in others in front of it, which Swinnerton regards as of importance in establishing the morphology of the bone. The ridge for the insertion of the arcus palatini muscles is characteristic of the ventral surface of the parasphenoid. There are usually two of these ridges as in *Amiurus*, but in *Scomber* (Allis, 1903) they have fused into a single ridge along the middle line of the bone.

Before Huxley, the parasphenoid was regarded as the homologue of the mammalian basisphenoid and was called the 'sphenoidae basilare.' Huxley (1864) recognized the peculiar relation of this bone to the ventral surface of the cranium and denied this homology because it extended beneath the anterior bones of the cranium and posteriorly beneath the basioccipital, and was easily detached from the chondrocranium. He limited the distribution of the parasphenoid to the branchiate vertebrates and this idea was prevalent until Sutton (1884) maintained that the bone was present in the higher groups and that it was the representative of the vomer of the mammals. Its great development in the fishes and in the Amphibia is due to the weak base of the chondrocranium. With the highly ossified condition of the sphenoidal cartilages of the Mammalia the bone was no longer needed as a support of the cranium and so it became a part of the septum of the nasal passages.

The development of the parasphenoid from membrane below the anterior basicranial fenestra has been known for a long time in many groups and, as noted above (page 43), the development in *Amiurus* is typical. In some of the lower teleosts, among which is *Osteoglossum* (Ridewood, 1904), the parasphenoid bears teeth, but it is not known whether they are primarily an integral part of the developing bone or have fused with it later.

*The suprasphenoid.* This bone in *Amiurus* is in a very unspecialized condition as compared with those teleosts which have an interorbital septum. It lies cerebral to the parasphenoid and is firmly fused to it (Fig. 7). It occupies the floor of the cavum cranii between the optic and trigeminal nerves; anteriorly it overlaps the orbitosphenoid, posteriorly the prootic. Laterally, between the foramina for these nerves, it interdigitates with the alisphenoid. As stated above, it is developed from membranous connective tissue between the trabeculae in the fenestra hypophyseos (Fig. 32). It has all the characters common to the suprasphenoid bone of the other teleosts, except the eye muscle relations. The homologies of this bone have been discussed earlier in the paper, as the terminology used is based principally upon its developmental relations.

*The alisphenoids.* These are a pair of bones, one on each side of the cranium between the optic and trigemino-facial foramina (Figs. 7, 20). Their ventral ends are separated externally from each other by the parasphenoid, and inter-

nally by the suprasphenoid. The former is usually sutured to the alisphenoid between the ventro-posterior margin of the optic foramen and the antero-ventro-margin of the trigemino-facial foramen. An anterior process of the alisphenoid extends ventrally as the anterior margin of the optic foramen, descending in the orbital wall as far as the orbitosphenoid. This interdigitation between the alisphenoid and orbitosphenoids continues dorso-posteriorly to the anterior end of that part of the frontal which overlaps the dorsal margin of the alisphenoid. The latter extends higher up in the cranial wall than does the more anteriorly situated orbitosphenoid. Above the trigemino-facial foramen the alisphenoid interdigitates with the anterior margin of the ventral part of the sphenotic, the line of interdigitation continuing forward between the sphenotic and the frontal. The sphenotic projects broadly above this part of the alisphenoid and a concavity is formed between them by the lateral projection of the alisphenoid. The ligament of the dilator operculi muscle is inserted on the roughened face of the alisphenoid in this concavity. The very anterior margin of the hyomandibula articulates with the posterior edge of the alisphenoid below the ligament insertion.

The ophthalmic branch of the trigeminus issues from the cranium through a foramen in the wall of the alisphenoid just postero-dorsal to the optic foramen, and extends anteriorly along a ledge above the latter. This foramen is the outer end of a short canal which proceeds posteriorly within the alisphenoid and has its cerebral opening near the posterior ventral margin of the internal surface of the bone (Fig. 7). The ophthalmic branch of the facial passes anteriorly through a more dorsal canal. Although its cerebral opening is just dorsal to the cerebral opening of the ophthalmic branch of the trigeminus, the external opening of the canal is farther forward than the external opening of the latter, and lies just posterior to the point where alisphenoid, frontal and orbitosphenoid meet. The manner in which these nerves are included within the bone is first seen in the 32 mm. stage (Fig. 4). Up to that time the nerves, after leaving the cartilage, extend free across the orbit, but with subsequent development they are gradually enclosed by the ossification of the connective tissue around them in connexion with the alisphenoid cartilage, so that eventually the adult condition is reached. The ventral end of the bone is formed by the ossification of the original membranous wall between the optic and trigeminal nerves (Fig. 32). This method of development of the alisphenoid from cartilage and membrane has been noted in *Salmo* (Schleip 1903).

The cerebral surface of the alisphenoid bone is smooth and presents the same relations to the surrounding bones as the external except at its ventral margin, where it is overlapped by the dorsal projection of the suprasphenoid (Fig. 7). The anterior margin of the alisphenoid, where it meets the orbitosphenoid, has not entirely replaced the underlying cartilage, which still shows through the thin surface lamella. There is probably some cartilage yet remaining between the dorsal cap of the alisphenoid and the ventral surface of the

frontal. The inner ends of the canals for the ophthalmic branches of the fifth and seventh nerves have been discussed above. McMurrich noted both of these canal openings, but only one nerve. He stated (1884b) that the upper opening "opens into the interior of the bone like other similar foramina which perhaps, have a nutritive function." In reality this foramen is the posterior end of a canal for the passage of the ophthalmicus branch of the facial nerve and not for a blood vessel. He also says that the ventral margin of the alisphenoid bone articulates with the basisphenoid (suprasphenoid, auct.) alone and does not touch the parasphenoid, but from a study of sections through this region, I think that para- and suprasphenoids are fused along the ventral margin of the bone and that the external surface is the parasphenoid and the internal, the suprasphenoid. I cannot find any point where alisphenoid meets the prootic as he maintains, but since this is common in most of the teleosts, there is a possibility that such was the condition in the specimens he studied although it is present in none of mine.

An historical review of the various names which this bone has borne since the earliest descriptions of it by Meckel, Arendt, Cuvier, and others, is given by Owen (1848), Vrolik (1873), and Starks (1901). Since the orbitosphenoid was lacking in the perch, which Cuvier used as his type, he caused confusion in the literature by regarding the alisphenoid as the homologue of the ala orbitalis and the prootic as the ala magna. Hallman (1837), as noted above, recognized the true homology of the bone and called it the ala magna, because of its relation to the first branch of the trigeminus. Huxley's work on the homologies of the basal part of the cranium helped to define the criteria for the identification of the bone as it is known today. Owen, at the same time, ignored Huxley's conclusions and regarded the bone as the orbitosphenoid because of its relation to the optic nerve. At present all ichthyologists agree that this bone has approximately the same relations to the surrounding bones as has been described for *Amiurus* and the term alisphenoid is in common use. Yet, as stated above, some do not regard it as the homologue of the greater wing of the mammals.

In fishes with a well developed interorbital septum, the orbitosphenoid is wanting and the alisphenoid is correspondingly reduced in size. Scomber (Allis, 1903), the Loricati (Allis, 1910), and *Alepocephalus* (Gegenbaur, 1878), are good examples of this limitation in the development of the bone. In spite of its size in these forms, the alisphenoid usually encloses a small foramen for the ophthalmic branch of the fifth nerve, just posterior to the optic. In *Megalops* (Ridewood, 1904) the alisphenoids meet in the roof of the cranium. In *Gasterosteus* (Swinnerton, 1902) the alisphenoids are lacking, their place being taken by dorsal spiculae of the parasphenoid.

The Cyprinidae (Sagemehl, 1891) approach nearest to the type of alisphenoid found in *Amiurus*, and in *Catostomus* there is the same anterior projection of the bone. Stannius (1853) recognized this high development of the ali-

sphenoid as typical of the cyprinoids and siluroids, basing his observations on *Silurus glanis* and *Cyprinus carpio*. Vrolik's figure of *Silurus glanis* also shows a well developed alisphenoid.

The developmental relations of the bone have been discussed above, but it may be added that the roughened surfaces for the attachment of muscles and ligaments of the adult is developed from the muscle fascia and connective tissue surrounding the perichondrial lamella of the alisphenoid cartilage.

*The sphenotics.* Next to the frontals, these are the most conspicuous paired bones on the dorsal surface of the cranium (Fig. 10). Each is subquadrangular in shape and has long interdigitating margins, projecting into the surrounding bones. Anteriorly, each interdigitates with the posterior margin of the frontal, the line between these two bones being continuous posteriorly with the sphenotic-supraoccipital interdigitation. The posterior margin of the dorsal surface of the bone extends in between the squamoso-pterotic and the posterior end of the supra-occipital, almost touching the transverse crest of the latter. The anterior lateral margin of the sphenotic is raised slightly, so that a dilatator groove is formed along the latero-dorsal surface, for the insertion of part of the dilatator operculi muscle and ligament. The surface of the bone is without ridges and the lateral line canal ossification has sunken below the surface and is invisible from above. The only foramina on the dorsal surface of the bone are several for the passage of twigs of the ramus oticus of the facial.

The lateral surface of the bone is grooved for articulation with the hyomandibula (Fig. 20). This surface is ossified, but the face of the hyomandibula which articulates with it, is still cartilage. The beginning of the ossification in this region has been shown earlier (Figs. 19, 33). The articular facet is continuous posteriorly with a similar groove on the lateral face of the squamoso-pterotic, and below it the two bones are separated from each other by a narrow strip of cartilage, which extends ventrally as far as the prootic bone (Fig. 20). The line of interdigitation between sphenotic and prootic extends antero-ventrally from the ventral end of this piece of cartilage and continues as far anteriorly as the dorso-posterior margin of the trigemino-facial foramen. From this point as far forward as the mid-dorsal margin of the foramen the sphenotic alone forms the margin. Here it comes in contact with the posterior end of the alisphenoid and the suture between them extends dorso-ventrally as far as the region where the sphenotic meets the frontal. Viewed from above the ventro-external extent of the sphenotic is not very great.

The internal surface of the bone forms an almost square area in the cranial wall, from the dorsal margin of the trigemino-facial foramen to the supraoccipital (Fig. 7). Anteriorly it is in contact with the alisphenoid in the margin of the same foramen and above this with the frontal. The interdigitation with the frontal continues posteriorly as the line between sphenotic and supraoccipital. Posteriorly the sphenotic meets the prootic and the continuation of this suture to the supraoccipital is restricted by a small square of cartilage. A

shallow recess about in the center of the cerebral surface of the sphenotic contains the cerebral end of a canal through which the ramus oticus facialis passes and which emerges by several foramina on the dorsal surface as already mentioned. The anterior end of the recess for the anterior semicircular canal lies within the bone, but the canal itself does not extend to the end of the recess. The internal surface of the recess, noted above as filled with trabeculae (Figs. 33, 36), has now entirely ossified so that this part of the sphenotic bone is solid. Cartilage between the inner and outer lamellae of the bone has not been entirely replaced, traces of it occurring between the pterotic and the sphenotic. The large cartilaginous roof present in the 32 mm. stage between the supraoccipital and the medial dorsal edge of the sphenotic (Fig. 3) has been covered by perichondrial ossification continuous with the latter. The lateral line ossification has become an integral part of the bone, although restricted to a very small area (Fig. 11). There are no sense organs within the lateral line canal in the sphenotic nor are there any tubules leading to the exterior.

From Cuvier (1826) to Parker (1872), the sphenotic was regarded as the homologue of the postfrontal of the reptiles, and so named. Parker first called it the sphenotic and described it in *Salmo* as an ectosteal ossification of the otic capsule above the ampulla of the anterior semicircular canal, thus grouping it with the other otic bones described by Huxley (1864). Up to that time the criterion for the homology of this bone was based upon morphological rather than ontogenetical relations. Vrolik (1872) devotes a short paragraph to the names which this bone has borne in the older literature, but calls it the postfrontal and describes it in the teleosts as a 'perichondrostische ossifikation,' the equivalent of a dermal bone of the present paper. In *Amia* (Bridge, 1877; Sagemehl, 1884) the bone was called the postfrontal, until Allis (1898) revised the nomenclature of the problematical bones of this animal, and called it the postorbital ossification. The use of this term was unfortunate because he had already applied the name postorbital to a bone of the infraorbital series as the homologue of the reptilian postorbital. The name postfrontal was given to the superior dorsal bone of the infraorbital chain and from his definition of it, I have followed him in naming its homologue in *Amiurus*. In *Scomber* (Allis, 1903), he uses the same confusing terms, postorbital bone and postorbital ossification for postorbital and sphenotic respectively, justifying his terminology, on the basis, that they should not convey any relationship to the bones of the higher groups. The term sphenotic as used by Parker is more expressive of the developmental relations of this bone than the terminology of Allis and, as this bone is strictly a piscine and avian ossification, no confusion will arise through its use. Allis (1910) evidently has changed his views and has called the homologous bone of the *Loricati*, the sphenotic.

Ridewood (1904) maintains that the term postfrontal should be retained because it describes the uppermost surface of the bone, the lateral line element. According to Allis (1898) the postfrontal never fuses with an underlying peri-

chondrial ossification and hence this part of the sphenotic is not comparable to the true postfrontal. He does not attempt to explain to what bone this dermal derivative may be compared. In *Amiurus*, as in many other teleosts, the perichondrial ossification on the chondrocranium is fused with a dorsally lying lateral canal ossification (Figs. 19, 33). McMurrich also noticed this in his work on *Amiurus*. If the postfrontal of *Amiurus* is to be regarded as the superior infraorbital bone, then this lateral line canal ossification, above the sphenotic, must be an element which has no homologue in the higher groups and is developed for the protection of the canal alone, eventually sinking in and becoming intimately connected with the perichondrial ossification. That it takes only a minor part in the formation of the broad roof of the bone can be seen by the way in which the major part of the bone is developed medial to it on the surface of the otic capsule.

The homologies of the remaining parts of the bone in the Teleostomes are easy to trace. The lateral face is usually grooved for articulation with the hyomandibula and is related in *Amiurus* to the anterior and posteriorly situated bones. In most Teleostomes the sphenotic does not have the ventral extent found in *Amiurus*, nor does it occupy as much of the dorsal surface of the cranium. In *Scomber* (Allis, 1903) and the *Loricati* (Allis, 1910), the relations of the ramus oticus facialis are comparable to the condition in *Amiurus*.

There is a great deal of cartilage within the bone and sometimes, as in *Salmo*, there is no internal ossification. The relation of the bone to the recess for the anterior semicircular canal is a constant feature, although in most fishes the canal extends only part way into it.

In some of the Cyprinidae the lateral part of the dorsal surface of the bone is grooved for the insertion of the dilator operculi ligament and muscles as in *Amiurus*. In other teleosts this fossa lies more upon the posterior margin of the frontal than upon the sphenotic. It may be said however, that the sphenotic usually forms a part of the dilator fossa.

*The prootics.* These bones form the floor and most of the lateral walls of the cavum cranii, posterior to the suprasphenoid and the foramina for the passage of the seventh nerves. As noted above (Figs. 4, 26), they develop around the anterior parachordals and the ventral part of the otic capsules. They are fused with each other in the median line of the cranial floor, below and posterior to the hypophysis. A large amount of the original cartilage remains in both the lateral and ventral parts of the bone, for the most part encased in a perichondrial osseous lamella and continuous with the cartilage of the surrounding bones (Fig. 7). That part of the bone which forms the posterior margin of the trigemino-facial foramen is exceedingly thin and transparent. In tracing the development it was noted that the cartilage which originally formed the posterior margin of the foramen in the 10 mm. stage did not keep pace with the growth of the cartilage of the surrounding parts, so that in the 32 mm. stage,

a thin lamella of bone formed the margin, as if the cartilaginous connexion between the parachordal and otic capsule had been stretched, until only the ossified perichondrium remained between them (Fig. 4). The other thin part of the bone lies near its posterior margin, just dorso-posterior to its suture with the basioccipital (Fig. 20). This part was formed from the outer lamella alone, as is stated in the discussion of the 32 mm. stage, and was solid cartilage in the 10 mm. stage.

The external surface of the bone is smooth, except for a shallow depression near the dorsal margin where the adductor hyomandibularis is inserted (Fig. 20). The bone is almost square in outline and has anterior, dorsal, and ventral edges serrated, where they overlap the other bones. The posterior margin is straight and is separated from the exoccipital by a thin strip of cartilage. Antero-dorsally it interdigitates with the sphenotic below the hyomandibular facet, but takes no part in the formation of the latter. Dorso-posteriorly this line of interdigitation continues between the prootic and the anterior end of the pterotic. Ventro-anteriorly it is overlapped by the parasphenoid and behind by the basioccipital. No foramina are present in the body of the bone for the passage of nerves or blood vessels as these all leave by the trigemino-facial foramen.

The internal surface of the bone is not as regular in outline nor does it present the same smoothness as the outer (Fig. 7). As remarked above, the bones of the two sides are fused in the middle line and their anterior edges are overlapped by the posterior margin of the suprasphenoid bone which extends from the ventral margin of one trigemino-facial foramen across the floor of the cranium to the other. There is a shallow depression in the floor of the cranium just behind this contact with the suprasphenoid, the sella turcica, for the hypophysis. The floor of the sella is very thin, but immediately posterior to it there is a massive ridge, the dorsum sellae, which is continuous posteriorly with the bulk of the basioccipital bone. This is not completely ossified, but considerable cartilage, continuous with that within the basioccipital, remains between the inner and outer lamellae.

The median section shows the relations of the prootics to the parasphenoid and basioccipital in this posterior region (Fig. 7). The recessus sacculorum project anteriorly into the posterior ends of the prootics and medial to them the transverse suture between the inner lamella of the prootics and the basioccipital is visible. In the 32 mm. stage (Fig. 27) a thin horizontal lamella from the median cartilage extends laterally above the anterior end of each recessus to the ventral edge of the otic capsule, but no lamella was yet formed on the floor of the recessus. In the adult, this basal lamella is present and, together with a lamella of the basioccipital, extends ventrally into the recess. The prootic lamella forms both floor and side walls of the recessus and is fused with the ventral face of the horizontal lamella, but the basioccipital lamella meets a descending lamella of the exoccipital half way up in the lateral wall. Thus in

the dorsal part of the lateral wall of each recessus sacculi the posterior margin of the prootic is sutured to the exoccipital. This suture continues laterally in the labyrinth recess as far as the base of the lateral septum semicircularis. The bulk of this septum persists as cartilage and separates the lateral margin of the prootic from the exoccipital. A lamella of the prootic extends up on the anterior face of the cartilage and its dorsal end is separated from the posterior ventral margin of pterotic part of the squamoso-pterotic and the inner lamella of the supraoccipital by cartilage. Anteriorly, in the floor of the lateral recess, the prootic meets the pterotic and the line between them extends anteriorly as far as the outer end of the anterior septum (Fig. 7). This septum is also partly cartilage, and the prootic lamella embraces its ventral surface and is confluent with the inner surface of the wall of the anterior recess, formed by a vertical projection from the floor of the prootic. In the younger stage this wall was cartilage and showed the beginnings of perichondrial ossification on both its cerebral and labyrinthine surfaces. The cartilage at the cerebral end of the septum anterior separates the prootic lamella from the supraoccipital.

I have not been able to find the eye-muscle canal which McMurrich (1884b) described as occurring between the prootic, parasphenoid and basioccipital. These bones are very tightly pressed together in this region and there is no space between them.

Cuvier (1826) first described this bone in the fishes as the homologue of the human ala magna. About the same time Meckel (1824) recognized it as the homologue of the petrosal because of its relation to the labyrinth and the facial nerve. His ideas were further elaborated by Hallmann (1837), who revised the nomenclature of the bones in this region, but retained this name. Stannius (1853) called it the ala temporalis because of its general similarity to the temporalis of the mammals. As is well known Huxley (1864) homologized this bone in *Esox* with one of the three ossification centers of the petrosal part of the temporalis of man and called it the prootic. Some of the modern authors have, nevertheless, retained the term petrosal, although on comparison with the petrosal of mammals it can be compared only to the part defined by Huxley.

The prootic is one of the constant bones of the piscine cranium and usually has the same general relations to the anterior semicircular canal and the facial nerve. In those teleosts which have an eye-muscle canal (*Salmo*, *Scomber*, the *Loricati*, etc.) the facialis issues through the bone, separate from the trigeminus. In groups in which the eye-muscle canal is not developed, as in *Amiurus*, the facialis issues through a notch in the anterior edge of the prootic. In most forms, whether an eye-muscle canal be present or not, the median ventral ends of the bones of the two sides are fused in the floor of the cranium. The eye-muscle canal usually lies ventral to the median ends of these bones, which form its roof. The parasphenoid in such cases forms the floor and part of the side walls of the canal. The presence of a large amount of cartilage within the bone has been remarked in *Scomber* and the *Loricati* (Allis), and in some of the

Cyprinidae (Sagemehl, 1891), and in *Salmo* (Parker, 1872). It is not remarkable to find it where the chondrocranium is persistent to a very great degree in other parts, but in *Amiurus*, where there is a great deal of ossification, it is significant of the primitiveness of this region.

In some of the Clupeoid fishes (Ridewood, 1904), the basicapsular fenestra, which occurs in larval *Salmo* (Parker, 1872; Gaupp, 1906), is a constant feature in the adult between the prootic, parasphenoid and basioccipital bones.

In *Perca* (Cuvier, 1826; Hallman, 1837), *Carpio* (Cuvier, Hallman, Stan-  
nius, 1853; Sagemehl, 1891), *Pleuronectes* (Cole and Johnson, 1901), the prootic forms the lower part of the hyomandibular facet. In *Salmo*, *Scomber*, the *Loricati*, and many other forms, there are separate foramina in the bone for the passage of carotid arteries, jugular vein and the hyomandibularis ramus of the facialis. In *Amiurus*, some, but not all of the blood vessels communicate with the internal parts of the cranium through the large trigemino-facial foramen. In *Scomber*, the external surface is grooved as in *Amiurus* for the insertion of the adductor hyomandibularis; the same thing is possibly true for most fishes, but has not been stated in the descriptions.

*The squamoso-pterotics.* In the 32 mm. stage both the squamosal and the pterotic were in their initial stages and the perichondrial and dermal elements which make up the adult compound bone were just beginning to fuse in the wall of the otic capsule above the lateral semicircular canal (Fig. 31). In places, the cartilage had been resorbed and the inner and outer lamellae were connected by osseous trabeculae. The lateral line canal, which in the older stage, is invisible from above, at that time formed a slight ridge on the dorsal surface of the cartilage and was fused to the underlying perichondrial ossification. In the adult, the outer surfaces of the bone, both lateral and dorsal, are made up almost entirely of ossified membrane and muscle fascia (Figs. 6, 10, 20). This led some authors who had not carefully studied the development, to conclude that the whole bone was entirely a dermal ossification, and hence comparable to the squamosal part of the temporalis of man.

The lateral line canal ossification of the adult becomes an integral part of the dorsal surface of the bone and connects postero-laterally with the superior end of the opercular-mandibular canal and the main lateral canal of the body (Fig. 11). The former passes into the latero-posterior corner of the bone from the dorsal one of two subtemporal lateral line ossicles, the margin of which is fastened to the squamosal part of the bone by ligamentous tissue. Before leaving the squamosal that part of the canal which is to pass into the body issues to the surface, and runs posteriorly on it for a short distance before passing into the post-temporal. There are two sense organs in the lateral line canal within the squamoso-pterotic.

The dorsal surface of the squamosal part of the bone is subtriangular in outline and with serrated edges overlaps the surrounding bones. Anteriorly it

articulates with the sphenotic, medially with the supraoccipital, and posteriorly with the epiotic (Fig. 10).

There is no temporal fossa, but there is a space between the squamosal and pterotic parts, which may be a remnant of it. The latero-posterior end of the bone projects broadly and on its surface is the groove for the lateral line canal before it enters the post-temporal. Connective tissue fibres extend from its margin to the margin of the operculum, holding the latter in place.

The ventral surface of the bone is grooved and ridged for the insertion of the fibres and ligaments of the adductor operculi muscle (Fig. 6). This face of the bone is sculptured more than is the dorsal; it is formed by the ossification of the fascia and connective tissue external to the original perichondrial ossification. The latter ossification shows in two places on this surface—anteriorly on the margin below the hyomandibular articular surface, and posteriorly on the postero-ventral margin of the bone. In both of these places the bone is a very thin lamella separated from the bone nearest it by cartilage; the cartilage is continuous within the lamella of both of the bones. Anteriorly it is separated from the sphenotic and posteriorly from the exoccipital by cartilage. Between these two bones the outer lamella interdigitates with a similar lamella of the prootic, and close examination of this part shows considerable cartilage yet remaining beneath these layers. Postero-dorsally it interdigitates with the epiotic.

The dorso-lateral margin of the bone is grooved for articulation with the hyomandibular and is entirely ossified in all parts. As noted above, this facet for the hyomandibular continues anteriorly on to the sphenotic. There are several foramina in the ventral surface of the bone which lead into its interior, but do not communicate in any way with the *cavum cranii*. Several blood vessels and some loose connective tissue fill this space and the region immediately external to it.

Internally, the pterotic lamella is limited to the lining of the recess for the lateral semicircular canal and the anterior wall of the posterior (Fig. 7). In the floor of the recess it interdigitates with the prootic lamella, but is separated from the internal lamellae of the other bones—supraoccipital and epiotic—by the cartilage of the lateral septum and the roof of the recess. In the very lateral extremity of the recess, the cartilage has been resorbed, a process beginning in the 32 mm. stage (Fig. 31). For the most part, however, inner and outer perichondrial lamellae are separated by persisting cartilage.

The squamosal part of the bone is the only part found in *Amia* (Sagemehl, 1884), and it is distinctly separated from the chondrocranium by a space filled with connective tissue and the anterior ends of the body musculature. There is also a lateral line element fusing with the squamosal in *Amia* just as in *Amiurus*, and the canal, upon leaving the squamosal, pursues the same course. *Amiurus* repeats the condition which Sagemehl described for most of the *Characinae* and *Cyprinidae*, where a squamosal unites with a pterotic element.

This author has stated that in some of the forms with a thick cutis, the lateral line canal ossification never fuses with the squamosal element and hence both are independent ossifications. The internal relations of the pterotic lamella are the same as in *Amiurus*, and cartilage persists to a great extent within it and the surrounding bones. In those forms where the sphenotic is small (*Scomber*, *Salmo*, the *Loricati*, etc.) and limited to the anterior edge of the otic capsule, the squamosal element of the bone extends anteriorly and articulates with the frontal. The lateral line canal, which in *Amiurus* passes first through the sphenotic and thence into the squamosal, in these forms passes directly from the frontal into the squamosal. The squamosal element of the bone is usually limited medially by the parietal, but in *Amiurus* it has fused with the supraoccipital. There is always a ridge or a groove on the ventral surface of the squamosal part for the support of the shoulder girdle, and another groove on the lateral face, for articulation with the hyomandibula.

Cuvier called this bone the 'os mastoideum,' homologizing it with the mastoid portion of the temporal bone of human anatomy. Hallman (1837) recognized it as the homologue of the squamosal element of the temporal, and, regarding the bone from adult conditions, this was a logical conclusion, as he did not study its development. Both of these authors used the cranium of *Perca* and Hallman also made a detailed study of the cranium of *Cyprinus*. Huxley (*Esox*) called the bone the squamosal and did not recognize its relation to the chondrocranium. Parker (1872) says that he tried to point out to Huxley the fact that in *Salmo* the bone developed in connexion with the wall of the lateral semicircular canal and hence was comparable to another otic ossification center. Huxley would not entirely grant his views, but in his book remarked that in the opinion of Parker, the bone under consideration was a true otic bone. Thus it remained for Parker (1872) to designate it as the pterotic in *Salmo*. According to this view it was developed entirely as a chondrocranial bone and did not have the elements which were recognized later by Gaupp and Schleich. They called it the dermo- and autosquamosal according to the suggestion of Van Wijhe (1882) for the naming of the parts of mixed bones. Sagemehl found both elements in the *Characinidae* and the *Cyprinidae*, but called the whole the squamosal. Allis calls this bone by differing names in his papers, and in his work on the *Loricati* (1910) designates the bone as the pterotic followed by squamosal in parenthesis, giving an erroneous synonymy to the first term.

*The epiotics.* These are a pair of bones on the latero-posterior dorsal angles each of the cranium. Each lies between the squamoso-pterotic, the supraoccipital and the exoccipital of its side (Figs. 9, 10). Each is pyramidal with the apex on the posterior surface of the cranium and has three faces, the first on the dorsal surface of the cranium, the second on the posterior surface below the apex, and the third on the latero-ventral surface (Fig. 6). The dorso-anterior surface of the bone bears a strong vertical crest, along the anterior face of which some opercular-mandibular muscle fibres have their insertion. The median

prong of the post-temporal bone is firmly fastened by ligament to the posterior surface. A ligament of the trapezius muscle is attached to the crest below the post-temporal. The crest itself continues medially on the supraoccipital.

At first sight this part of the bone appears as an isolated element, because the squamoso-pterotic bone extends in beneath the crest, and apparently separates this part of the bone from the more posterior portion. Closer inspection shows that the crested part of the bone and the more posterior part are a continuum, although the latter is rugose and concave just behind the crest, giving the impression that the crested part of the bone is a separate piece. The posterior part of the bone slopes ventrally to form part of the posterior surface of the cranium (Fig. 9). Medially it is separated from the supraoccipital by a strip of cartilage which continues around the ventral margin of the bone, there separating it from the exoccipital. Above this, on the lateral surface of the cranium it interdigitates with the pterotic part of the squamoso-pterotic. This portion of the epiotic is thin and concave ventrally for the insertion of fibres of the adductor operculi muscle. It does not develop from the perichondrium of the otic capsule, but by ossification of connective tissue around the ends of the muscle fascia.

The posterior surface of the bone is corrugated for the insertion of the ends of the trapezius muscle fibres. Thus the external surface of the epiotic bone is covered with a superficial ossification developed from muscle fascia, which covers most of the outer perichondrial lamella.

The internal surface of the bone forms the posterior and dorsal walls of the recess for the posterior semicircular canal. Most of the wall is completely ossified and the cartilage has been resorbed except along the margins of the bone. In the earlier stages this part of the otic capsule had an inner lamella which was connected across the walls of the recess by osseous trabeculae (Fig. 38), and which now forms the solid central part of the posterior wall of the recess.

Although it has been definitely demonstrated by Huxley, Parker, Schleip and Gaupp, that the epiotic bone of the teleosts is a distinct otic ossification developed from the posterior dorsal part of the otic capsule wall, the Cuvierian name 'occipitale externum' is still prevalent in the literature. Sagemehl (1884) modified the term and called it the 'exoccipitale' in his work on *Amia*, the Characinidae and the Cyprinidae. Allis followed him and in all except his most recent papers has named it according to Sagemehl, although this introduces confusion with the true exoccipitals.

In all of the teleosts this bone lies at the posterior dorsal angle of the cranium as in *Amiurus*, and bears more or less of a crest for articulation with the post-temporal part of the shoulder girdle. Sometimes the epiotic is limited more to the dorsal surface of the posterior region of the otic capsule, but usually a part of it extends ventrally as the hinder wall of the posterior semicircular canal. Its homologies are evident throughout the teleosts and even in most ganoids it is a well developed ossification.

*The supraoccipital.* This is a large unpaired bone which forms the median cranial roof behind the frontals. Its anterior margin is divided into halves by the posterior end of the posterior fontanelle, on the margins of which it meets the frontals (Fig. 10). The portions of the bone along the fontanelle are raised above the level of the surrounding bones and form a ridge which is continuous anteriorly with a similar ridge on the frontals and posteriorly with the medial surface of the occipital spine. Muscles of the opercular and mandibular apparatus have their insertion along the sides of these ridges. At the base of the ridge the supraoccipital interdigitates with both the sphenotic and squamosopterotic.

Near the posterior margin of the dorsal surface, a crest, continuous with that of the epiotic, meets the longitudinal ridge at right angles and a cavity is formed by their intersection (Fig. 10). The crest curves postero-dorsally and forms the lateral margin of the dorsal surface of the spina occipitis, a triangular osseous splint which projects posteriorly from the dorsal surface of the cranium. Between the crests of the two sides the dorsal surface of the spine has the shape of a trough, the floor of which is irregularly excavated for the insertion of muscle fibres. The ventral edge of the spine is connected to the posterior dorsal surface of the supraoccipital proper by a thin osseous sheet, which, as noted above (Fig. 29), is developed by the ossification of the connective tissue between the anterior muscles.

Behind the crest the main portion of the supraoccipital bone descends on the posterior surface of the cranium as far as the exoccipital bones (Fig. 9). Laterally, there is an interdigitation between the upper medial margin of the epiotic and the supraoccipital, which continues anteriorly into the crest. The ventrolateral margin of the supraoccipital is separated from the epiotic by a strip of cartilage, continuous ventrally with that between the epiotic and exoccipital. The ventral margin of the supraoccipital interdigitates with the dorsal margin of the exoccipital in the wall of the foramen magnum, where there is also a strip of cartilage between them. The supraoccipital forms a very small part of the wall of the foramen. Just above the foramen the supraoccipital is embraced by the anterior ventral surface of the anterior spine of the compound vertebra, which, as stated in the account of the development of this region, is the neurapophysis of the third neural arch, the first two neural arches being modified as parts of the Weberian apparatus. The whole external surface of the posterior face of the bone is rugose and bears ridges for the attachment of muscle fibres.

The internal surface of the bone is very smooth and for the most part is only a superficial lamella on the cartilage around the dorsal ends of the septa semicircularia (Fig. 7). Anteriorly, on each side, it interdigitates with the frontal and laterally with the sphenotic; each side is separated from the posterior end of the sphenotic by a small area of cartilage at the dorsal end of the septum semicircularis anterior. The bone extends over the cartilage between

the anterior and lateral septa, but does not meet the pterotic lamella which lines the lateral recess. It forms an osseous sheath on the anterior face of the posterior septum and encloses the fenestra for the passage of the posterior membranous canal. Below this fenestra it meets the exoccipital. The inner end of the canal for the passage of the ramus lateralis accessorius of the facial nerve and the jugular vein lies in a recess in the bone above the fenestra. In median section this bone shows itself to be well ossified and thick, especially in that region which forms the margin of the posterior fontanelle. Laterally, the inner and outer lamellae are separated by cartilage.

This is one of the best developed bones of the adult teleost cranium and usually has a long posteriorly projecting spine attached to its dorsal surface. Cuvier recognized it in *Perca* and stated that, while it might possibly be regarded as the interparietal, he preferred to describe it as the homologue of the reptilian supraoccipital. Hallman (1837) figures it in *Cyprinus* and *Perca*, but gives no detailed description. Parker (1872) was the first one to describe the development of the bone in detail in the teleosts, as arising from perichondrial lamellae on the occipital arch and synotic tectum, between the parietals, and touching the frontals anteriorly. In *Salmo* the margins of the bone are rounded and there is not the spiculate serrate edge found in *Amiurus*. Sagemehl (1885) described the bone in the *Characinidae* briefly, and commented upon the extent of the occipital spine, with the remark that from its relations to the muscle, there was evidence that it had been developed from the fascia between them and has secondarily fused with the main part of the bone developed on the occipital arch. In his discussion of the bone in the *Cyprinidae*, he states an hypothesis for the development of the bone from the ganoid condition, where it is wanting, by assuming that the occipital arch in the teleosts, upon which the supraoccipital bone developed, arose from the assimilation of the first vertebrae in a ganoid ancestor of the teleosts, and that there is no evidence for regarding the bone as a derivative of the dermal plates in this region of *Polypterus*, *Acipenser*, *Lepidosteus* and *Amia*. Loomis (1900) has shown in the fossil ganoids of Kansas, that the supraoccipital is absent, although present in the fossil teleosts. Zittel (1884, 1893) and Woodward (1898) have described this same condition in the fossil *Teleostomes*. But in a previous discussion, it was concluded that the vertebra at the anterior end of the vertebral column were not serially homologous in the different groups and that segments can be intercalated and excalated. So instead of regarding the supraoccipital as the homologue of a neural process of the ganoids, it must be assumed to be a new part which is intercalated as a new formation in the teleosts, but at what time this intercalation took place there are no fossil records. The homologue of the supraoccipital plates of *Polypterus* is the *spina occipitis*. This has been developed from connective tissue above the occipital arch and is fused to the underlying supraoccipital ossification. In the *Stegocephali* (Fritsch, 1883), there are a pair of supraoccipital plates corresponding to those

of *Polypterus*, and going yet higher in the vertebrate series we find that two pairs of connective tissue ossifications have been described attached to the dorso-anterior margin of the cartilaginous supraoccipital in man, the interparietals and the preinterparietals (Ficalbi, 1890; Ranke, 1899). The latter are inconstant, but the former may be the bones which correspond to the spina occipitis of the teleosts and the supraoccipital plates of the *Stegocephalans*.

McMurrich (1884b) states that in *Amiurus* the dorsal surface of the spina occipitis is perforated with foramina for the passage of tubules connected with the 'mucous' canal system; an error since the canal system has no branches in the posterior part of the cranium outside of the squamosal part of the squamoso-pterotic. Further, he says that the 'ascending branch' of the first spinal nerve (my hypoglossus) issues from the cranium through the foramen for the ramus lateralis accessorius facialis. As I have not been able to find a dorsal branch of this nerve in either the younger or the older specimens, I cannot agree with him

*The exoccipitals.* The floor and side walls of the foramen magnum are formed by the paired exoccipital bones (Fig. 9). Nearly the whole margin of each bone is smooth except for a few interdigitating spicules on the epiotic and supraoccipital edges. It is separated anteriorly from the pterotic part of the squamoso-pterotic and the posterior margin of the prootic bone by a strip of cartilage which continues ventro-posteriorly between it and the antero-dorsal margin of the basioccipital. On the posterior surface of the cranium it is separated from the epiotic by the cartilage, but interdigitates with the ventral margin of the supraoccipital as far as the wall of the foramen magnum where cartilage is present between the bones.

The anterior ventral surface of the bone is pierced by two foramina, a small anterior one for the glossopharyngeal and a larger one immediately posterior for the vagus (Fig. 20). The ossification separating them is a very delicate osseous spicule and was originally cartilage. Just behind the vagus foramen there is a sharp, upwardly curved prong, to which the transcapular bone is attached. This latter bone has developed from the ossification of a ligament between the shoulder girdle and the cranium (Fig. 37). Ventral to the articulation of the transcapular with this bone, the surface of the exoccipital is rugose for the attachment of the fibres of the shoulder girdle muscles. On the posterior surface of the cranium the bone is concave medial to the base of prong, and at the bottom of this concavity there is a minute foramen for the passage of the hypoglossus nerve. A flange of the bone projects posteriorly behind this foramen at right angles to the posterior surface of the cranium, forming part of the lateral wall of the foramen magnum. This part of the bone develops from the ossification of the membranous sheet, present in the younger stages, posterior to the hypoglossus, and fuses with the ventral end of the occipital arch. The posterior ventral margin of the bone is fused with the dorsal surface of the thickened basioccipital.

Within the cranium, the anterior margin of the bone interdigitates with the prootic as far laterally as the base of the lateral septum semicircularis, and medially as far as the roof of the recessus sacculi (Fig. 7). Behind the lateral septum semicircularis, the exoccipital lamella extends laterally over the floor of the recess for the posterior semicircular canal and part way up its posterior wall. It is separated by cartilage from the more lateral and dorsal pterotic and epiotic lamellae. The inner ends of the foramina for the glossopharyngeal and vagus nerves lie in this part of the bone. Medial to the posterior recess, a part of the bone extends out dorsally and, with the supraoccipital, forms a wall between the recess and the cavum cranii. At the base of this wall a horizontal process extends medially above the recessus sacculi and meets a similar process from the other side to form the roof of the sinus impar. The ventral surface of this process meets a splint from the basioccipital, which forms the side wall of the cavum sinus imparis and the roof of the recessus sacculi of that side. The lateral wall of the recessus sacculi is formed by exoccipital and basioccipital lamellae.

The foramen for the hypoglossus nerve lies posterior to and above the lateral end of the horizontal process. The latter forms the ventral margin of the foramen magnum, and between it and the dorsal surface of the basioccipital the sinus impar leaves the cranium to divide into the atria sinus imparis. The posterior ventral end of the exoccipital is fused with the basioccipital.

The exoccipital bone is one of the most constant bones throughout the vertebrate series. It is fairly well developed in all higher groups of ganoids, although considerable cartilage remains between the inner and outer lamellae. As in *Amiurus*, it forms the floor and side walls of the foramen magnum and there is usually a gap of cartilage in the dorsal margin of the foramen where in *Amiurus* the supraoccipital lies. In some teleosts—*Salmo*, *Citharinus*, and *Catostomus*—the cartilage persists in this region.

The anterior margin of the bone usually encloses the ninth and tenth nerves, either in a single foramen or an anterior and a posterior opening, and ossification usually starts in the cartilage around these foramina. The intercalated nerves are secondarily enclosed in the posterior part of the bone, as in *Amiurus*. In the Cyprinidae (Sagemehl, 1891), this foramen is larger and is divided into two parts, one for the ventral and the other for the dorsal root of the nerve. The dorsal foramen is very large in *Catostomus*, *Cyprinus*, and *Cobitis*, and, above the nerve, is filled with lymphatic tissue continuous with the contents of the saccus paravertebralis of the Weberian apparatus. Sagemehl claims that the larger has arisen by the fenestration of a single original foramen such as occurs in *Amiurus*.

Ostariophysian teleosts have a median horizontal process on each exoccipital, which, with its fellow of the opposite side, forms the cranial floor above the sinus impar and the recessus sacculorum. Actual contact of the exoccipital with the surrounding bones is not usually the case, because cartilage per-

sists between them. In this same group of fishes there is usually a ligament extending from the basioccipital to the shoulder girdle (Sagemehl, 1885), which he says is the homologue of the transcapular process of *Amiurus*.

The synonymy of this bone has been given by Owen (1848), Vrolik (1873), and Starks (1901). To their list of synonyms may be added the name given to this bone by Gaupp (1906), *pleurooccipitale*. Of all the names, *exoccipital*, suggested by Owen, is the briefest, and most comprehensive of the relations of the bone; *pleurooccipitale* has no excuse.

*The basioccipital.* This is the most posterior bone on the ventral surface of the cranium and is fused on its ventral face to the anterior centrum of the compound vertebra of the spinal column. The bulk of the bone lies in this immediate region and thins out anteriorly on the ventral and lateral surfaces of the cranium (Fig. 6). Its ventro-anterior margin is overlapped by spicules of the parasphenoid and its dorsal anterior surface by the posterior margin of the suprasphenoid and the prootic (Fig. 7). The dorso-lateral margin of the anterior end of the bone interdigitates externally with the extreme posterior ventral margin of the prootic (Fig. 20). Behind this interdigitation the basioccipital is separated from the antero-ventral margin of the exoccipital by cartilage until the two exoccipitals fuse posteriorly. Below this fusion the posterior face of the basioccipital is circular and deeply concave (Fig. 9). The edges of the concave anterior face of the centrum of the first vertebra is fused with the periphery of this face of the basioccipital and in the space enclosed between the faces is filled with gelatinous notochordal tissue. A small space in the ventral surface of the basioccipital just anterior to its fusion with this centrum remains unossified and is filled with cartilage, the remnant of the hypochordal cartilage of the 32 mm. stage (Fig. 38).

The internal surface of the bone is hollowed out for the reception of the sacculi. It forms the median crest between the recessus sacculorum and part of their floor and side walls. The dorsal surface of the crest is concave, forming the floor and walls of the *cavum sinus impar*. In the side wall of each recessus the internal basioccipital lamella meets the descending lamella of the exoccipital of that side. In the 32 mm. stage this had already completely ossified and so in the adult there is no cartilage left in the walls of the recessus except between the margins of the bones. Considerable cartilage yet remains in the basal plate between the posterior end of the prootic and the basioccipital (Fig. 7). There is no trace of the intercranial notochord so prominent in the younger stages.

The transcapular bone has part of its attachment to the lateroventral surface of the basioccipital (Fig. 9).

The basioccipital of the teleosts is very constant in its morphological relations. As in *Amiurus*, its posterior face is concave where attached to the centrum of the first vertebra and the gelatinous mass is nearly always present between them. In the *Ostariophysi* the sacculi penetrate more deeply into

the substance of the basioccipital than they do in other teleost groups, but the sacculi always have a relation to the dorsal surface of the bone. The interdigitation of basioccipital with parasphenoid, and articulations with prootic and exoccipital, are common characters. The processes on the bone for articulation with the transscapular process are peculiar to the Siluridae. The pharyngeal processes of the Characinidae and Cyprinidae, extending from the ventral surface of the basioccipital to the wall of the swim-bladder, are not found in other teleosts. Allis (1910) mentions a groove on the dorsal surface of the basioccipital in the Loricati, which he claims as the homologue of the cavum sinus imparis of the Ostariophysi. The basioccipital throughout the teleosts is usually excluded from participation in the formation of the foramen magnum by the union of the posterior ends of the exoccipitals above it or by the presence of the sinus impar.

The bulk of the bone is developed from the posterior parachordalia and the ossification of the intercranial notochord. In some of the Cyprinidae considerable cartilage remains in those parts of the bone which form the walls and floor of the recessus sacculorum. In all of the teleosts, the notochord disappears in that part of the basioccipital anterior to the vertebral articular surface. In the forms with an eye-muscle canal, the basioccipital forms its posterior floor.

*The premaxillaries* are a pair of bones forming the anterior end of the upper jaw and are closely fused with each other in the mid-ventral line of the cranium. They have no ascending process, such as occurs in *Salmo*, *Scomber*, *Alepocephalus* and other teleosts, but are closely fused to the ventral surface of the supraethmoid bone. They curve posteriorly on each side to form the osseous floor of the nasal fossae and are attached by ligament to the palatine and maxillary bones dorso-posteriorly. The ventral surface of each bone is covered with teeth, which, as mentioned in the younger stage are only secondarily connected with it (Fig. 15).

*The maxillaries.* Each maxillary bone (Fig. 15) lies latero-posterior to the premaxillary, embedded in the connective tissue forming the lateral margins of the upper lips. Each is toothless and serves as a support for the elongate, laterally extending, maxillary barbel. This lateral position of the maxillary is common among the teleosts and occurs in *Amia* also. In *Salmo*, the bone is continuous posteriorly with the premaxillary and bears a series of teeth on its ventral surface. In *Scomber* it lies partly internal to the premaxillary and has an articular surface for it. In the Loricati the bone has a long posterior extent and overlaps the mandible. In none of these forms is it as small as in *Amiurus* where it has a slender styliform shape and is held in position partly by connective tissue. It is in actual contact with the palatine bone, articulating with it by means of a small ball and socket joint, the latter lying on the palatine.

*The palatines.* These bones retain the same shape and relations as in the younger stages, although now much larger in size (Fig. 15). Ossification has proceeded in all parts and there is only a core of cartilage left. Each palatine is a slender dumb-bell shaped ossification lateral to and below the ectethmoid process with which it has articulated from its earliest stage. The anterior ventral end is grooved for the articulation with the maxillary, and the pre-maxillary is attached to these two bones by tough connective tissue. As earlier, so now, the palatine has no actual contact with the pterygoquadrate ossification. In *Salmo* the bone is continuous posteriorly with the bones of the pterygoid arch and bears teeth on its ventral surface. In the Characinidae, the palatine bone has varying sizes and shapes, but it is developed on cartilage continuous posteriorly with the cartilage within the pterygoid bones. In *Erythrinus*, the maxillary articulates with the palatine in the same manner as in *Amiurus*, but the palatine does not extend as far forward. In *Scomber* (Allis, 1903), the palatine is fused with the anterior bone of the pterygoid series and bears teeth.

*The ectopterygoid.* This bone develops by the ossification of a sheet of connective tissue ventral to the palatine and connected with it by connective tissue (Fig. 15). The posterior margin interdigitates with the anterior margin of the large metapterygoid. McMurrich (1884b) described this bone as 'number four' and stated that it could not be homologized with a pterygoid bone because it was developed from membrane. Schleip (1903) found that it developed from membrane in *Salmo* and that it is separated from the pterygoid cartilage by connective tissue and yet maintains that it is the homologue of the ectopterygoid of other teleosts. The bone is very small, quadrate in outline, with delicate sculptured radiating lines. In *Salmo* it is longer and thinner than in *Amiurus* and has more of the character of the corresponding bone in *Amia* (Van Wijhe, 1882), the Characinidae and the Cyprinidae. There is no entopterygoid in *Amiurus*.

*The metapterygoid.* This large bone is developed around the pterygoid part of the pterygoquadrate cartilage. It is quadrangular in outline and interdigitates anteriorly with the ectopterygoid, posteriorly with the hyomandibular and ventrally with the quadrate (Fig. 15). No cartilage persists in any of the visible parts of the bone. Medially it is attached to the lateral surface of the cranium by a sheet of muscular and ligamentous tissue. A mesopterygoid occurs in most teleosts between the meta- and ectopterygoids, but in *Amiurus* the two interdigitate. In *Scomber* a small strip of cartilage intervenes between the metapterygoid and the quadrate and there is a space between the former and the elongate hyomandibular bone. In *Salmo* (Parker, 1873) the bone is not nearly as great in extent, occupies a position entirely dorsal to the quadrate and is separated from the latter, as in *Scomber*, by cartilage. It does not interdigitate with, but overlaps the hyomandibular.

In *Megalops* (Ridewood, 1904), a large ectopterygoid hinders its anterior extent and it overlaps the hyomandibular posteriorly. In *Pleuronectes* (Cole and Johnson, 1901), it is smaller than in *Amiurus* and lies posterior and dorsal to the quadrate. The small metapterygoid of the Characinidae is separated from the ectopterygoid and quadrate by cartilage and there is also a large foramen between it and the latter.

*The quadrate.* This bone is situated at the ventro-anterior end of the hyomandibular suspensorial apparatus (Fig. 15). It is grooved on its inferior face for articulation with the mandible. It is rather small, and firmly fused to the surrounding bones, although there is a small area between it and the hyomandibular, where the underlying persisting cartilage shows between the bones. Its posterior face interdigitates with the preopercular bone. Mc-Murrich (1884) states that the cartilage mentioned as occurring between the bones is the symplectic and that in perfectly dried skulls there is a space between the hyomandibular and the quadrate due to the absence of cartilage.

*The hyomandibular.* This large bone connects the quadrate with the cranium. It is immovably fused with the latter and if one moves, both must. A process of the bone projects from the anterior edge to the lateral surface of the alisphenoid which is hollowed out for its reception. Posterior and dorsal to this point of contact the hyomandibular articulates with the side of the cranium in a groove which has been described in connexion with the sphenotic and squamoso-pterotic bones. There are several ridges on the lateral surface of the bone along which the adductor muscles are attached (Fig. 15). Just above its interdigitation with the preopercular is a foramen for the passage of the ramus hyomandibularis facialis. The knob for the articulation of the operculum has ossified and is overlapped by the ventral surface of this bone, which is hollowed out as a socket for movement on the knob.

In *Salmo* (Parker, 1873), the hyomandibular does not have the anterior and ventral extent that it has in *Amiurus* and it is isolated from the surrounding bones by cartilage. Parker does not figure the foramen for the hyomandibularis nerve, but from Gaupp's figure (1906) of the foramen in the younger stage of *Salmo*, it is evident that the nerve passes farther forward than in *Amiurus*. In the Albulidae and Mormyridae, and other lower teleosts, the hyomandibular does not have so great an anterior, posterior, or ventral extent as in *Amiurus*, and usually a small symplectic element comes between it and the quadrate. The preopercular does not articulate with the hyomandibular as closely as in *Amiurus*. In all of the teleosts the hyomandibular has a knob on its posterior edge for the articulation of the operculum; in some of the Characinidae cartilage persists at this point.

*The dentary.* The teeth which are borne on the lower jaw are attached to the medial dorsal surface of this bone, from the symphysis as far back as the dentary-articulare interdigitation. The bone retains the shape and relations

which it had in the younger stages. It tapers anteriorly where it meets the fellow of the opposite side and is deeper posteriorly (Fig. 15). The inner surface of the bone is hollow for the reception of the anterior end of Meckel's cartilage. The ventro-anterior surface is perforated by a series of six pores for the passage of tubules of the enclosed mandibular lateral line canal (Fig. 11). The canal issues from the mandible through the more posterior pore and enters the connective tissue surrounding the quadrate and thence passes into the preopercular. I agree with McMurrich that the dentary is a mixed bone and is the result in part of the ossification of a portion of Meckel's cartilage. The developmental stages show that the bone is at first arises entirely from the connective tissue membrane around the cartilage fused with a lateral line ossification; later part of Meckel's cartilage ossifies and fuses with it (Fig. 24).

*The articulare.* This is a triangular bone at the posterior end of the mandible and is grooved on its posterior face for articulation with the quadrate (Fig. 15). It does not contain a lateral line element. The internal dorsal surface is flat and gives attachment to the muscles which move the lower jaw. Considerable cartilage persists between the outer and inner lamellae. The bone bears no teeth and interdigitates anteriorly with the dentary, which also extends posteriorly in a groove on its ventral surface.

*The preopercular.* The mandibular-opercular lateral line canal enters this bone from the connective tissue surrounding the posterior ventral end of the quadrate (Figs. 11, 15). The bone is fused solidly to the quadrate ventrally, and to the hyomandibular dorsally. A small process projects down behind the quadrate and the opercular canal passes into this part.

The posterior edge is ridged and projects above the more posterior lying operculum. The dorsal end of the bone extends for a short distance behind the hyomandibular. There is a small foramen in the middle part of the bone for passage of a branch of the hyomandibularis facialis as it descends after passing through the hyomandibular.

*The subtemporals.* These are two small bones lying dorsal to the preopercular and above the posterior margin of the hyomandibular (Figs. 11, 15). They contain the dorsal end of the opercular lateral line canal which passes through them into the squamosal. They are very thin and the canal in passing through them, lies in a groove rather than in a tube, the ventral and lateral walls of which are thicker than the very thin roof. Only one such bone, having the same relations to the lateral line canal and the squamosal is found in this region of *Salmo*. Parker (1872) called it the supratemporal, but the supratemporal of the stegocephalans always lies medial to the squamosal so that this bone could not be its homologue. Ridewood (1904) suggests the term adopted here and says that the real supratemporal of *Salmo*, between the back of the squamosal and the post-temporal, was overlooked by Parker, but it is really

larger than the subtemporal. Sagemehl (1885) states that these bones are present in many of the Siluroids.

*The opercular apparatus.* This consists of three bones; a large dorsal operculum and two smaller ventral bones, the inter- and suboperculum, (Fig. 15). The operculum spreads out posteriorly in a wide arch and articulates anteriorly with the hyomandibular knob. It is heavily sculptured on its external surface, tapers ventrally, and at its inferior apex the short quadrangular interoperculum is attached by ligamentous tissue and interpolated between it and the posterior end of the articulare. The suboperculum is smaller and lies medial to the interoperculum.

## SUMMARY

1. The chondrocranium of *Amiurus* is platybasic.
2. In the chondrocranium of the 10 mm. *Amiurus* there is no internasal septum; the epiphysial bar is the only part of the chondrocranium dorsal to the brain; it divides the opening in the roof of the primitive skull into an anterior and a posterior fontanelle.
3. The olfactory foramen lies in a sagittal plane and is very large in comparison with the olfactory tract. A solum nasi is present. The ectethmoid process, a short transverse projection between the nasal fossa and the orbit, is perforated by the ophthalmicus superficialis trigemini. An orbital foramen is present posterior to the ectethmoid process.
4. Trabecular and alisphenoid cartilages form the margins of a large fenestra in the lateral wall of the cranium for the passage of the optic, oculomotor, trigeminal, abducens, and facialis nerves. The fenestra is closed by membrane at the 10 mm. stage, except where the nerves pass.
5. The alisphenoid cartilage is the homologue of the ala magna of the mammalian chondrocranium.
6. The cavum labyrinthii opens directly into the cavum cranii; there are three septa semicircularia; no basicapsular fenestra is present; the glossopharyngeal and vagus nerves issue from the cranium between the otic capsule and the parachordal plate. The otic capsules are fused posteriorly with the occipital arch; a synotic tectum is lacking in the 10 mm. *Amiurus*. The hyomandibular articular surface lies external to the lateral semicircular canal.
7. The parachordal cartilages lie lateral to the intercranial notochord, are fused anteriorly with the trabeculae, dorso-laterally with the otic capsules, and posteriorly with the occipital arch. The notochord forms the axis of the posterior part of the solid parachordal plate. The sacculi lie in recesses on the dorsal surface of the parachordal plate on each side of the notochord.
8. The ventral ends of the occipital arch are fused with the parachordals posterior to the vagus foramen; the posterior end of the arch is inserted into the anterior end of the third neural arch. The hypoglossus nerve has dorsal and ventral roots united within the vertebral canal and a single lateralis ramus issuing between the occipital arch and the anterior process of the scaphium. The nerves posterior to the hypoglossus have the rami characteristic of true spinal nerves and alternate with the neural arches. Two pairs of myotomes are present lateral to the occipital arch, but their innervation by the nerves in

this immediate region could not be clearly made out. The two pairs of myotomes following these are innervated by the second and third pairs of post-vagal nerves.

9. The beginnings of the premaxillary and maxillary bones are present in the 8 mm. *Amiurus*.

10. The palatine cartilage is independent of the pterygoquadrate, and the latter is fused to the hyomandibular.

11. Ossification is present in the skull of the 32 mm. *Amiurus*. The large dorsal fontanelles of the 10 mm. stage are limited to mere slits by the frontal and supraoccipital ossifications; the epiphysial cartilage persists, but lies relatively further posterior; a rudimentary tegmen cranii and synotic tectum are present; a massive cartilaginous internasal septum divides the olfactory tracts; the olfactory foramina lie in a transverse plane.

12. The supraethmoid bone has both membrane and perichondrial ossifications entering into its composition. The perichondrial ectethmoid ossification is fused with a connective tissue ossification on the lateral margin of the ectethmoid process. The foramen orbito-nasale lies relatively more posterior than in the 10 mm. stage; perichondrial ossifications appear on the margin of the orbital foramen.

13. The fenestra hypophyseos is closed by the orbitosphenoid, parasphenoid, suprasphenoid, and prootic ossifications.

14. The intercranial extent of the notochord is apparently less than in the 10 mm. stage, but this is due to the greater relative growth of the cartilaginous parts surrounding it.

15. The suprasphenoid bone is developed from membrane in the floor of the cranium and is not the homologue of the basisphenoid of the mammalian cranium, but is a bone peculiar to the teleosts.

16. A squamosal ossification, developed from membrane, fuses with the pterotic ossification; as the latter has no homologue in the mammalian petrosal, the resulting bone of the adult cannot be a temporalis, but must be regarded as a squamoso-pterotic.

17. The spina occipitis of the supraoccipital bone arises from membrane and is the homologue of the supraoccipital plates of the Stegocephali and probably of the interparietal element of the mammalian cranium.

18. The skull of the adult *Amiurus* is well ossified, although considerable cartilage persists in the ethmoid and otic regions. The adult cranium resembles, in many points, the crania of some of the Characinidae and Cyprinidae.

## PLATE I

## EXPLANATION OF PLATE

Fig. 1.—Lateral view of model of chondrocranium of *Amiurus* 10 mm. long.

<i>alis</i>	alisphenoid bone	<i>oph V</i>	foramen for ophthalmicus superficialis trigemini
<i>asa</i>	anterior semicircular canal	<i>oph VII</i>	foramen for ophthalmicus superficialis facialis
<i>asl</i>	lateral semicircular canal	<i>op pro</i>	opercular process
<i>csp</i>	posterior semicircular canal	<i>or f</i>	orbital foramen
<i>ect pro</i>	ectethmoid process	<i>ot c</i>	otic capsule
<i>ep b</i>	epiphysial bar	<i>pal</i>	palatine
<i>eth</i>	ethmoid plate	<i>pch</i>	parachordal
<i>eth cr</i>	ethmoid cornu	<i>pq</i>	pterygoquadrate cartilage
<i>f o n</i>	foramen orbito-nasale	<i>r ot VII</i>	ramus oticus facialis foramen
<i>hmd</i>	hyomandibular	<i>tr</i>	trabecula cranii
<i>hmds VII</i>	hyomandibularis branch of VII	<i>vis</i>	visceral arches
<i>hy</i>	hyoid arch	<i>IX</i>	glossopharyngeal foramen
<i>inth</i>	interhyal	<i>X</i>	vagus foramen
<i>m</i>	Meckel's cartilage		
<i>occ</i>	occipital arch		
<i>olf</i>	olfactory foramen		

## PLATE II

## EXPLANATION OF PLATE

Fig. 2.—Dorsal view of chondrocranium of *Amiurus* 10 mm. long.

<i>alis c</i>	alisphenoid bone	<i>m</i>	Meckel's cartilage
<i>ca</i>	foramen for internal carotid artery	<i>occ</i>	occipital arch
<i>csa</i>	anterior semicircular canal	<i>olf</i>	olfactory foramen
<i>csl</i>	lateral semicircular canal	<i>oph V</i>	foramen for ophthalmicus superficialis trigemini
<i>csp</i>	posterior semicircular canal	<i>oph VII</i>	foramen for ophthalmicus superficialis facialis
<i>ect pro</i>	ectethmoid process	<i>ot c</i>	otic capsule
<i>ep b</i>	epiphysial bar	<i>pal</i>	palatine
<i>eth</i>	ethmoid plate	<i>pch</i>	parachordal
<i>eth cr</i>	ethmoid cornu	<i>r ot VII</i>	ramus oticus facialis foramen
<i>f bcr</i>	fenestra basicranii anteriorius	<i>tr</i>	trabecula cranii
<i>f h</i>	fenestra hypophyseos	<i>3ne</i>	third neural arch
<i>f o n</i>	foramen orbito-nasale		
<i>hmd</i>	hyomandibula		

## PLATE III

## EXPLANATION OF PLATE

Fig. 3.—Model of chondrocranium of 32 mm. *Amiurus*, dorsal view. On the right side only cartilage parts are shown, on the left the bones as well, cartilage being stippled to contrast with the bones.

Fig. 4.—Same, ventral view, cartilage only on left side, cartilage and bone on right of drawing.

<i>alis</i>	alisphenoid bone	<i>ot c</i>	otic capsule
<i>alis c</i>	alisphenoid cartilage	<i>pal</i>	palatine
<i>ant font</i>	anterior fontanelle	<i>pch</i>	parachordal
<i>bo</i>	basioccipital	<i>pf</i>	postfrontal
<i>csa</i>	anterior semicircular canal	<i>pmx</i>	premaxillary
<i>csl</i>	lateral semicircular canal	<i>po</i>	postorbital
<i>csp</i>	posterior semicircular canal	<i>post font</i>	posterior fontanelle
<i>ect</i>	ectethmoid	<i>pro</i>	prootic
<i>ect pro</i>	ectethmoid process	<i>ps</i>	parasphenoid
<i>ep</i>	epiphysial	<i>pt</i>	post-temporal
<i>epo</i>	epiotic	<i>r ot VII</i>	ramus oticus facialis foramen
<i>eth</i>	ethmoid plate	<i>sbo</i>	suborbitals
<i>eth cr</i>	ethmoid cornu	<i>se</i>	supraethmoid
<i>f h</i>	fenestra hypophyseos	<i>so</i>	supra occipital
<i>f o n</i>	foramen orbito-nasale	<i>sph</i>	sphenotic
<i>fr</i>	frontal	<i>spoc</i>	spina occipitis
<i>la</i>	lacrimal	<i>sps</i>	supraorbital canal
<i>mx</i>	maxillary	<i>sq ptr</i>	squamoso-pterotic
<i>na</i>	nasal	<i>tc</i>	tegmen cranii
<i>occ</i>	occipital arch	<i>tp</i>	tubule pore of lateral line canal
<i>olf</i>	olfactory foramen	<i>tr</i>	trabecula cranii
<i>oph V</i>	foramen for ophthalmicus superficialis trigemini	<i>vo</i>	vomer
<i>oph VII</i>	foramen for ophthalmicus superficialis facialis	<i>II</i>	optic foramen
<i>os</i>	orbitosphenoid	<i>V-VII</i>	foramen trigemino-facialis
		<i>IX</i>	glossopharyngeal foramen
		<i>X</i>	vagus foramen

## PLATE IV

## EXPLANATION OF PLATE

Fig. 5.—Model of mandibular and suspensorial apparatus of 32 mm. *Amiurus*, lateral view; cartilage stippled.

Fig. 6.—Cranium of adult *Amiurus*, ventral view.

Fig. 7.—Same, median section and internal surface, cartilage stippled.

<i>alis</i>	alisphenoid bone	<i>or f</i>	orbital foramen
<i>art</i>	articulare	<i>os</i>	orbitosphenoid
<i>bo</i>	basioccipital	<i>pre</i>	preopercular
<i>csi</i>	cavum sinus imparis	<i>pro</i>	prootic
<i>dent</i>	dentary	<i>ps</i>	parasphenoid
<i>ect</i>	ectethmoid	<i>q</i>	quadrate
<i>ep b</i>	epiphysial bar	<i>r ot VII</i>	ramus oticus facialis foramen
<i>eth cr</i>	ethmoid cornu	<i>sa</i>	septum semicircularis anterius
<i>ex</i>	exoccipital	<i>se</i>	supraethmoid
<i>fr</i>	frontal	<i>sl</i>	septum semicircularis laterale
<i>hmd</i>	hyomandibula	<i>so</i>	supra occipital
<i>hmd gr</i>	hyomandibular groove	<i>sp</i>	septum semicircularis posterius
<i>hmds VII</i>	hyomandibularis branch of VII	<i>sph</i>	sphenotic
<i>hypg</i>	foramen for hypoglossus nerve	<i>sps</i>	supraorbital canal
<i>int s</i>	internasal septum	<i>sq pt</i>	squamos opterotic
<i>mdc p</i>	mandibular canal pores	<i>sq ptr</i>	squamoso-pterotic
<i>mpt</i>	metapterygoid	<i>vo</i>	vomer
<i>op</i>	operculum	<i>II</i>	optic foramen
<i>oph V</i>	foramen for ophthalmicus superficialis trigemini	<i>V-VII</i>	foramen trigemino-facialis
<i>oph VII</i>	foramen for ophthalmicus superficialis facialis	<i>IX</i>	glossopharyngeal foramen
		<i>X</i>	vagus foramen

## PLATE V

## EXPLANATION OF PLATE

Fig. 8.—Transverse section through middle of otic capsule and parachordal plate of 32 mm. *Amiurus*.

Fig. 9.—Posterior view of adult cranium of *Amiurus*.

Fig. 10.—Dorsal view of adult cranium of *Amiurus*.

Fig. 11.—Dorsal view of adult cranium and jaws, showing diagrammatically the course of lateral line canal, position of pores and sense organs with regard to the bones.

Fig. 12.—Transverse section through the posterior part of the occipital arch of 8 mm. *Amiurus*.

Fig. 13.—Transverse section through the scaphia of an 8 mm. *Amiurus*.

Fig. 14.—Transverse section through posterior orbital region, 8 mm. *Amiurus*.

<i>alis c</i>	alisphenoid cartilage	<i>ot c</i>	otic capsule
<i>ant font</i>	anterior fontanelle	<i>pch</i>	parachordal
<i>ant pro</i>	anterior process of the scaphium	<i>pf</i>	postfrontal
<i>art</i>	articulare	<i>po</i>	postorbital
<i>bo</i>	basioccipital	<i>post font</i>	posterior fontanelle
<i>br</i>	brain	<i>pre</i>	preopercular
<i>ca si</i>	canal sinus imparis	<i>pt</i>	post-temporal

## PLATE VII

## EXPLANATION OF PLATE

Fig. 24.—Transverse section through lower jaw of 60 mm. *Amiurus*, midway between symphysis and quadrate articulation.

Fig. 25.—Similar section, 32 mm. *Amiurus*.

Fig. 26.—Transverse section through the parachordal plate ventral to the vagus foramen, 32 mm. *Amiurus*.

Fig. 27.—Transverse section through anterior end of parachordal, 32 mm. *Amiurus*.

Fig. 28.—Same, a little farther posterior.

Fig. 29.—Transverse section through posterior part of occipital arch, 32 mm. *Amiurus*.

Fig. 30.—Transverse section through ethmoid region, 8 mm. *Amiurus*.

Fig. 31.—Transverse section through roof of lateral semicircular canal, 32 mm. *Amiurus*.

Fig. 32.—Transverse section through posterior orbital region, 32 mm. *Amiurus*.

<i>alis</i>	alisphenoid bone	<i>occ</i>	occipital arch
<i>alis c</i>	alisphenoid cartilage	<i>olf</i>	olfactory foramen
<i>ant pro</i>	anterior process of the scaphium	<i>pal</i>	palatine
<i>bo</i>	basioccipital	<i>pch</i>	parachordal
<i>csi</i>	cavum sinus imparis	<i>pro</i>	prootic
<i>csi</i>	lateral semicircular canal	<i>ps</i>	parasphenoid
<i>dent</i>	dentary	<i>ptr</i>	pteric
<i>end</i>	endorhachis	<i>r m</i>	rete mirabile of the internal carotid artery
<i>eth</i>	ethmoid plate	<i>r s</i>	recessus sacculi
<i>ex</i>	exoccipital	<i>sac</i>	sacculus
<i>fr</i>	frontal	<i>sca</i>	scaphium
<i>l</i>	lagena	<i>sn l</i>	first true spinal nerve, second post-vagal nerve
<i>ll c</i>	lateral line canal	<i>spoc</i>	spina occipitis
<i>l os</i>	lateral line ossification	<i>sq</i>	squamosal
<i>m</i>	Meckel's cartilage	<i>tr</i>	trabecula cranii
<i>mdc</i>	mandibular canal	<i>vg</i>	vagus nerve
<i>mx</i>	maxillary	<i>3ne</i>	third neural arch
<i>my</i>	myotomes		
<i>na</i>	nasal		
<i>na o</i>	nasal organ		
<i>nch</i>	notochord		

## PLATE VIII

## EXPLANATION OF PLATE

Fig. 33.—Transverse section through the roof of the anterior end of the otic capsule, 60 mm. *Amiurus*.

Fig. 34.—Transverse section through the synotic tectum, 32 mm. larva.

Fig. 35.—Diagram of nerve, neural arch and myotome relations of a larval *Amiurus*.

Fig. 36.—Transverse section through the anterior end of the anterior semicircular canal, 32 mm. *Amiurus*.

Fig. 37.—Transverse section through the posterior end of the basal plate, 32 mm. larva.

Fig. 38.—Transverse sections through the posterior end of the otic capsule, 32 mm. *Amiurus*.

Fig. 39.—Transverse section through the posterior part of the ethmoid region, 32 mm. *Amiurus*.

<i>a hm</i>	adductor, hyomandibularis	<i>nch</i>	notochord
<i>bo</i>	basioccipital	<i>ne 1-3</i>	neural arches 1-3
<i>csa</i>	anterior semicircular canal	<i>olf l</i>	olfactory lobe
<i>csi</i>	cavum sinus imparis	<i>or f</i>	orbital foramen
<i>csp</i>	posterior semicircular canal	<i>ot c</i>	otic capsule
<i>ect</i>	ectethmoid	<i>pal</i>	palatine
<i>epo</i>	epiotic	<i>pch</i>	parachordal
<i>eth</i>	ethmoid plate	<i>pt</i>	post temporal
<i>fr</i>	frontal	<i>r lat acc</i>	ramus lateralis accessorius facialis foramen
<i>hmd</i>	hyomandibula	<i>so</i>	supraoccipital
<i>hyp</i>	hypochordal cartilage	<i>sph</i>	sphenotic
<i>l o</i>	levator operculi	<i>s pv</i>	saccus paravertebralis
<i>l os</i>	lateral line ossification	<i>tp</i>	tubule pore of lateral line canal
<i>my 1-5</i>	myotomes 1-5	<i>vo</i>	vomer
<i>n 1-4</i>	post-vagal nerves 1-4	<i>X</i>	vagus foramen
